ORIGINAL ARTICLES.

THE PRINCIPLES OF THE TREATMENT OF FRACTURES BY SYSTEMATIC MOVEMENTS AND MASSAGE WITHOUT APPARATUS FOR IMMOBILIZATION.[1]

BY DR. LUCAS-CHAMPIONNIERE,

OF PARIS, FRANCE;

SURGEON TO THE HOTEL DIEU AND TO THE HOSPITAL BEAUJON IN PARIS, AND MEMBER OF THE ACADEMY OF MEDICINE.

As far back as the history of surgery is sufficiently detailed to give us any reliable information in the matter, we find that the treatment of fractures has always been regulated by the principle that immobilization of the fractured portions of bone should be promptly adopted and continued until repair was complete. In our own century this practise has been brought to perfection at least in the eyes of its advocates, and by the introduction of immovable apparatus.

The necessity for the immobilization of fractured bones has ruled surgery as a dogma admitting no doubt. The more perfect the immobilization the more rapid and more certain was the repair of the fracture considered, and the better was the surgeon's work performed. In principle and in practise, however, this system of immobilization is false and hurtful. Organs of movement were made to be moved; their health and their regular nutrition demand movement. The absolute suppression of it it such as is attempted in complete immobilization lowers the health of these organs and interferes seriously with the processes of repair.

It is now a long while since I first took up seriously the study of a number of facts which indicated that the rapid and perfect repair of certain types of fractures could be best accomplished without immobilization of any kind. My first observation on this subject was made in 1867. Since then I have published a series of papers[2] and have read a number of articles before various medical congresses and societies on the treatment of articular fractures; that is, fractures into joints by immediate passive movements instituted at the very beginning of the treatment.

In 1894 I formulated and began to teach a complete method of massage and systematic passive movements in the treatment of recent fractures. I published a first memoir in June, 1886, laying down the principles and expounding the practise of a method which was the result of a large number of personal observations in the matter. In 1895 I published a volume of considerable size on the treatment of fractures by massage and passive movements. This work contained a number of photographs in order to facilitate the study of the practical problems involved in the new method of treatment.

As my experience has grown wider I have seen better and better results from the treatment. In my service at present in the Hotel Dieu, as well as in the Hospital Beaujon, there are always a large number of fractures under treatment, and this method is always employed with results that leave nothing to be desired. Large numbers of practitioners in France and in foreign countries have accepted the new method favorably, although, of course, as might be expected, the great majority of surgeons have strenuously opposed it, as it was completely contradictory to the hitherto formulated principles of treatment of fractures. One of the surgeons who has best grasped the extreme importance of this method is Dr. Caldwell, an American, who has recently published a paper embodying certain practical points which he gathered in my service here in Paris.

It would be hard to exaggerate the importance of this revolution in the art of treating fractures, as it involves at least one-fifth of all the cases of fracture which, in the ordinary course of his practise, come to the surgeon for treatment.

Moderate movement favors the repair of fragments of a bone. Where movement is permitted the callus will be greater in quantity, will be more solid, and will be more rapidly thrown out. Any large amount of movement would inhibit the process of repair, or at least seriously interfere with it. Moderate movement preserves the vitality of the limb and preserves the suppleness of the articulations, the muscles, and the tendons. It entirely prevents the occurrence of any muscular atrophy. In every case, therefore, in which moderate movement does not threaten to cause the occurrence of deformity the limb should not be immobilized. On the contrary, an attempt should be made to keep up passively if not actively the movements that are necessary to the vitality of the parts.

In addition to this passive movement, massage, which especially favors the repair of traumatic lesions of muscles, tendons, ligaments, and articulations, may always be applied in practise on the single condition that the parts involved in the fracture do not thus become the subject of untimely interference with repair. We may apply massage to fractures immediately after an accident on condition that this massage be of the special kind that can be performed while the fractured member is properly supported. Massage, if undertaken in the ordinary manner, or if administered too energetically, would certainly result

[1] Translated.

[2] Société de Chirurgie, 1879-1880.

lamentably. The massage for a fracture ought to be applied to all parts of the limb, along the muscles, over the ligaments, and upon the hemorrhagic effusions, but never just over the site of the fracture nor directly upon the fractured ends of the bones. The massage ought to consist of gentle, repeated pressure always in the same direction from the periphery of the limb toward the trunk. It should be sufficiently prolonged. The length of the time spent at massage will depend somewhat upon the character of the lesion and the sensitiveness of the patient, but at least a quarter of an hour to twenty minutes once a day should be devoted to it.

The massage should never give pain. It should always be followed by an attempt at passive movements of the joints of the limb, which procedure must also be accomplished without pain.

The first effect of massage should always be to cause anesthesia of the part, so that all pain that has existed previously should disappear after its employment. The massage causes rapid resorption of all exudations and especially of hemorrhagic effusions. It preserves the suppleness of the part and prevents muscular atrophy. It exercises without doubt a most favorable and deep-seated action upon the nutrition of the limb, preserves its vitality, and keeps its functions in readiness for service instead of permitting them to degenerate by disuse.

When a member has been massaged and passive movement has been practised for the treatment of a fracture, the repair of the break is much more rapid than if apparatus for absolute immobilization were used. The deformity is much less marked because from the very beginning the muscular contraction, which is so powerful an agent in the production of these deformities, has been made to disappear. Finally, the member which has always remained supple, which has suffered no interference with its articulations, and no atrophy of its muscles, is not only more quickly, but completely cured, by the treatment. On the other hand, after the application of apparatus, especially of irremovable apparatus, a long period must elapse in order to complete the cure, and a second treatment by passive movement must be undertaken to overcome the consolidating action which the apparatus has produced.

These principles of treatment should be applied to all fractures. There is only one contraindication. If deformity threatens to result, that and that only should prevent the surgeon from using this method or hamper him in its application. We can treat absolutely without any apparatus by massage and mobilization alone the large majority of the fractures of the wrists, of the radius, and Colles' fractures. The larger number of fractures of the clavicle are amenable to the same method. In four years at the Hospital Beaujon I have had in my service more than sixty cases of fractures of the clavicle. I have treated all of them without apparatus, using only a simple sling, and not once having had occasion to apply any other form of treatment. All the fractures of the upper extremity of the humerus as far down as the insertion of the deltoid may be treated in this same way. All the fractures of the lower extremity of the humerus, all the fractures of the elbow, including those of the olecranon, most of the fractures of the fibula, a large number of the fractures of both malleoli, many of the fractures of the knee, and all of the fractures of the scapula are best treated in this way.

Besides these many of the fractures which cannot be treated with absolutely no immobilization yield better results when treated by a mixed method. The apparatus should be used after a preliminary massage and removed from time to time in order to permit of further massage. Even in fractures of the femur and of the humerus one can apply this mixed method in a large number of cases. By this means we can lessen and in a large measure do away with the inconveniences connected with the use of fixed apparatus, some form of which may be indispensable. In a number of cases I have even practised massage in compound fractures as soon as cicatrization of the wound was complete.

The secondary treatment of members in which luxations have taken place should also consist of massage and passive movements, which have not only proved to be of invaluable service in such cases, but have never in my experience exposed the patient in the slightest degree to the danger of a recurrence of the dislocation.

A few statistics will give an idea of the importance of this method of treatment in my service. I must state, however, that during ten years at the Tenon Hospital and at the Hospital St. Louis I had the massage in these cases done by my pupils under my personal direction, but since 1894 I have had so many cases of this kind to treat and the work has become so important a feature of my hospital service that I have placed it entirely under the charge of a special assistant, Dr. Dagron, and have committed entirely to his care the training of a number of students as trained assistants for this work. This number has especially included not a few women in order to be able to provide properly for all the necessities for massage in a large hospital.

In the last four years, 78 male and female nurses have taken these courses and have been employed in the service, becoming expert general masseurs and masseuses, as well as acquiring practical experience in massage for fractures. About 1200 patients in all have been under treatment. In 598 of these patients the lesions treated were really serious, and the observations made on them have been collated with a good deal of care. Of the 598 patients, 370 suffered from fractures distributed as shown by the following table:

Fractures of the clavicle, 60; fractures of the humerus, 45; fractures of the radius, 110; fractures of the forearm, 17; fractures of the olecranon, 13; fractures of the scapula, 3; fractures of the femur, 5; fractures of the tibia, 29; fractures just above the malleoli, 7; fractures of the fibula, 50; fractures of both malleoli, 31.

The dislocations treated by immediate massage have reached the number of 78; the sprains treated by this method were 69.

Among the fractures enumerated a certain number of those in the middle portion of the leg and those of the femur have been treated by the application of apparatus for immobilization during the intervals as well as by massage; but the immense majority of them have been treated either absolutely without apparatus or by very simple methods of fixation, and with a total exclusion of every sort of irremovable apparatus.

We have, therefore, in this method of treating fractures by massage and systematic passive movements without apparatus, a mode of treatment completely formulated, thoroughly established in practise, and very general in its application. I have applied it in recent years in my large service at the Hotel Dieu just as I have done for so many years at the Hospital Beaujon and with just as satisfactory results.

This method undoubtedly gives more rapid and satisfactory results than any other method of treating fractures that have been employed up to the present day. It requires, however, much more attention and much more personal care on the part of the surgeon than the use of apparatus which after careful application may be left undisturbed for days or even weeks. This method requires daily inspection and the application of treatment by some one ready and able to give the condition careful attention.

The massage for these cases, applied according to the principles which experience has taught me to be of special value, presents no serious difficulty; but it must not be confounded with the more or less rough practises which are ordinarily designated by the name massage. *The complete suppression of all pain during the primary and secondary treatment of fractures is the capital point in the matter.* It is this that shows that it is being properly and efficaciously applied.

SOME OF THE CAUSES OF FAILURE TO RELIEVE ASTHENOPIA AND ALLIED SYMPTOMS.[1]

BY F. W. MARLOW, M.D., M.R.C.S., ENGLAND,
OF SYRACUSE, N. Y.;
PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF SYRACUSE, N. Y.; OPHTHALMOLOGIST TO THE NEW YORK STATE INSTITUTION FOR THE FEEBLE-MINDED.

IT is by no means a rare thing for the ophthalmologist to meet with people who express the greatest disappointment, surprise, and sense of injury that a train of symptoms of years' duration, due, perhaps, to many complications, should not be relieved by the first glasses ordered.

Fifty years ago and less the matter of getting a pair of glasses was a much simpler affair than it is to-day, because at that period only the simpler errors were corrected. The subjects of asthenopia were advised long periods of rest, to adopt occupations not calling for close eye work, or were sent to the farm; while many, doubtless, became chronic neurasthenics.

To-day the causes of asthenopia are better understood, although in many directions our knowledge is very incomplete. Nevertheless, the recognition of the true nature of hypermetropia, the demonstration of astigmatism as a common error of refraction, and the establishment of the importance of latent deviations of the visual axes have greatly complicated the problem of fitting glasses, as well as widened the field of usefulness of the ophthalmologist.

If more people wear glasses than formerly, it is because the symptoms recognized to be due to eye-strain have greatly increased in number, and because of the demonstration of the importance of small errors, formerly neglected. With the increase in the complexity of the ocular problems presented for solution and in the number of those seeking relief from symptoms, there are necessarily more primary failures to relieve than was formerly the case.

Patients seek the advice of one oculist and if he fails to relieve them speedily, too often go to another. The second has to do the same work all over again, and, although he has the advantage of seeing the effect of the glasses prescribed by the first, is, perhaps, but little more successful.

The cases in which failure to relieve asthenopia occurs admit of fairly satisfactory classification on a clinical basis. They may be divided in the first place into two main classes; one consisting of *curable* cases, the other of *incurable* cases.

The curable cases may be divided into three groups. (1) In which the failure is the fault of the *patient*. (2) In which it may be said to be the fault of the *oculist*. (3) In which it may be said to be the fault of the *case*, or more specifically, due to the extreme latency of some of the errors of refraction and equilibrium.

The incurable cases may be placed under two headings. (1) Congenital asthenopes, people whose eyes are incapable of a normal amount of work, independently of their refraction and muscular condition, and of the general health. (2) Cases in which the symptoms are due to organic disease of the eye or brain, or to some general disease.

First, these incurable cases. There seem to be people who are born with eyes essentially weak; eyes in which no appreciable error of refraction or muscular equilibrium can be detected and in which nothing pathological can be discovered either by external or ophthalmoscopic examination, or eyes in which the apparently perfect correction of such errors as exist does not result in the desired relief; the general health of the patient being good. Such patients travel about from one oculist to another, seeking relief and finding none. The only credit which can be derived from the contact with these cases results from a realization and a frank statement of the situation, which, nevertheless, often requires a lapse of time and repeated examination for its appreciation. Cases

[1] Read by invitation before the Madison County, N. Y., Medical Society.

in which asthenopia is only partially relievable are quite common and require that the patient should adjust his activities and mode of life to the capacity of the eyes to work. The following is a good examples of this type:

March 27, 1897.—Mr. M., aged thirty-five, theological student, has been an athlete and an athletic trainer, in perfect general health. He complains that he can hardly read at all; that the muscles of his eyes ache; that his stomach troubles him if he does too much eye work. He had already consulted an oculist in some other city, who after using a mydriatic had given him weak convex spherical glasses. Examination showed his vision to be above the normal standard in each eye; that there was a low degree of hypermetropia, which was accurately corrected by the glasses already prescribed; that the muscular equilibrium was normal. Testing the power of adduction and abduction showed the latter to be relatively fuller than the former, and this afforded the only therapeutic indication in the case. He was prescribed prismatic exercise. Five days later when he came back the adduction was of normal measurement, but his condition was worse. He could not read as long. I saw him again about a month later. In the interval he had seen a well-known New York ophthalmologist who, recognizing the same relative weakness of the adduction, had given him prisms to wear during reading, but without benefit. Examination showed no change in any particular. I told the patient, therefore, that he must adjust himself to the situation; that lapse of time and prolonged rest would do for him all that could be done, at any rate, for the present.

I will not do more than refer to the groups of cases in which asthenopic symptoms are due to organic diseases of the eye, brain, or disturbance of general health. The true nature of such cases sooner or later becomes apparent.

We now come to the class of curable cases in which failure to relieve symptoms occurs for one of the reasons already given. In the first place, it may be the fault of the patient. There are many ways in which patients fail to carry out the directions given to them. Three errors stand out a little more prominently than the rest.

They neglect to wear their glasses constantly. This is a very common cause of failure. Patients also who have been already prescribed for with sufficient accuracy for reading, not infrequently seek advice because they still have symptoms referable to eye-strain, and in many of these cases all that is necessary is to advise the constant wearing of glasses already prescribed. Failure from this cause is sometimes the fault of the advisor as well as of the patient. The wearing of glasses to correct any, even the smallest error of refraction, changes entirely the previous working methods of the eyes, their accommodation, the relation of accommodation to conveyance, the relative tension of the extrinsic muscles, distribution of innervation, etc., and it cannot be regarded as surprising that some discomforts should occur at first. There is, indeed, a period of adaptation during which the new method of working is established. If the glasses are removed and the eyes are used without them they resume their old habits, which again are disturbed when the glasses are replaced. In some cases, indeed, there is not only a failure to relieve but even an aggravation of the symptoms from irregularity in the use of glasses. Such cases require no further comment.

There are other cases in which the patient wears his glasses constantly, but the period of adaptation is so prolonged and the discomforts attending the commencement of wearing glasses are so persistent that he not unnaturally comes to the conclusion that they must be incorrect. This is, of course, sometimes the true explanation of discomfort. There are, however, many cases in which perfectly corrected glasses give rise to prolonged annoyance and yet are finally worn with perfect comfort and ease. The following is a case in point.

Miss A. B., aged thirty, came for advice on March 31, 1891. Her eyes had troubled her since the age of two years when she suffered from sore lids; eyes always weak; as a girl was more out of school than in, on this account. For the past two years has suffered much from headache which has been a great deal worse lately. Has worn glasses eleven years. Until three years ago had worn smoked glasses, the chief trouble being photophobia, frequent inflammation of eyes and lids, and nausea. Since then she has worn a weak astigmatic glass 0.50c. 90° in each eye. Examination R. 6/9+0.75s.+0.75c. improves. L. 6/6 Hm. 1.D. After atropin she accepted R. +2D's.+1c. ax. 80°=6/6. L.+2.25Ds.+D.25c. ax. 150°=6/6, and was prescribed R.+1.75.+1c. 80°. L.+2D.s+0.25c. 150° for constant wear.

April 22.—She came back complaining of more headache, stating that sewing produced almost immediate pain in the eyes and lacrimation. Examination gave essentially the same result. Continued use of the glasses was insisted on. She left my office much discouraged, and I saw her no more until I accidentally met her in the summer of 1896. She then informed me that she gradually became comfortable with the glasses, which had entirely relieved her symptoms, and that she was wearing the same still.

This case is also an example of failure due to the omission to use a mydriatic; thus leaving the latent error unrecognized and uncorrected, to which reference will be made later.

Occasionally too much near work is attempted by those who, after suffering from asthenopia for years, have just had their refractive and other errors corrected. In many cases the resumption of work should be quite gradual.

Failure may be the fault of the oculist. I do not refer to the grosser errors which should be avoided by any well-trained and careful man, but to certain matters about which there still remains some difference of opinion in the profession. For

instance, he may neglect to correct low degrees of astigmatism, or, what amounts to the same thing, may fail to correct astigmatism with sufficient accuracy. Personally, I regard it as thoroughly established that low degrees of refractive error, especially astigmatism, are very effective in certain kinds of people in producing asthenopic disturbances.

In one of the well-known text-books we find the statement that "it is not usually necessary to correct astigmatism of less than one diopter." There are, doubtless, many persons in whom this amount of error seems to produce no discomfort, but in those who complain of asthenopic symptoms it is certainly a mistake to omit the correction of any plainly demonstrable astigmatism down to 0.25D, and it must be remembered that only those who have symptoms go to a physician.

A case I had some years ago impressed this fact very strongly upon my mind because the patient had during the ten years previous to consulting me been under the care of some of the most competent ophthalmologists in the country who had uniformly failed to benefit her. I ought to state that at that time the efficacy of low degrees of astigmatism to cause trouble was by no means so well appreciated as it is now.

March, 1889.—Mrs. J. P. D., aged fifty years: ten years ago began to suffer pain over the eyes and through the head after the use of the eyes. Suffers much from nervousness and insomnia. Cannot even look at distant objects without trouble. Headache twice a week. Sometimes has to go to bed on account of it. Examination showed one-quarter of a diopter of astigmatism in each eye; nothing else. I prescribed glasses correcting it for distance, and introduced the same correction for astigmatism into her reading glasses. The result was a practical cure. Three and a half years later she was able to use her eyes for two or three hours at a time for near work and headache occurred seldom.

The oculist may err in failing to correct the latent hypermetropia or in over-correcting myopia. These errors have been common in the past and are liable to continue to be so, for on the whole, there seems to be a tendency to attempt to dispense with a mydriatic, which at present is the most reliable means of demonstrating latent errors, on account of the annoyance to the patient, and of the difficulty which is occasionally experienced in getting used to glasses prescribed, perhaps injudiciously, after such preparation. While it is perfectly true that the attempt to wear a full correction of the refractive errors is often accompanied by annoying and discouraging symptoms, these symptoms are usually quite short in duration. It is equally true that the symptoms from which the patient seeks relief cannot be permanently removed without a correction of the latent as well as the manifest error.

The second case reported was a very good example of this fact. I am convinced that she could not have been relieved had the latent hypermetropia been left uncorrected. I do not mean to contend that a full correction of the latent error should be made in *every* case where we prescribe glasses. There are many cases in which symptoms are slight, and especially where patients will not wear their glasses constantly, in which a partial correction, at any rate, for a time, better meets the indications of the case. A perhaps more excusable cause of failure is the neglect to take into consideration the influence of latent strabismus. In many cases of asthenopia we find in addition to errors of refraction a tendency for the visual lines to converge, diverge, or deviate one above the other. Sometimes, some say as a general rule, the deviating tendencies are secondary to the refractive errors and disappear when the latter are corrected. But there are many cases in which the correction of these errors, however accurate, not only fails to relieve the symptoms but even aggravates them. It is easy to see how this may be the case. With the refraction corrected the retinal images are in greater or less degree indistinct, so that a more or less imperfect super-position of them is easily tolerated. But when the refraction is made accurate, clearly defined images are formed on the retinæ and an exact and constant correspondence of them is necessary or diplopia results. This increases the work, already excessive, of some of the muscles, and discomfort expressed in one way or another results.

I am referring now only to cases in which a sufficient latent deviation is detected before the first glasses are prescribed.

A case in point is that of Miss M. V., aged nineteen years, first seen May 18, 1891, who complained of pain on use of her eyes. Headache daily. She disclosed, on examination, before and after use of mydriatic, a moderate amount of Hy. with astigmatism and 12° of esophoria or more. As it seemed probable that the convergence was secondary in part, if not altogether, to the Hy. astigmatism, she was ordered simply the glasses for refractive error. They aggravated the symptoms. On June 15th she came with smoked glasses, having severe photophobia, entirely unable to read, etc. She showed a convergence of 21°. She was at once given prisms 3° each, bases out, which gave her immediate relief. To cut a long story short, the error was finally corrected by tenotomies, which gave complete and apparently permanent relief.

I have done little more than refer to the preceding groups of incurable and easily curable cases for various reasons. The latter groups require more persistence on the part of the patient or more careful attention to the demonstrable facts of the case on the part of the ophthalmologist. More than one prescription may be necessary before the glasses which give the greatest degree of relief can be decided upon.

The last group of cases is by far the most important, at the same time one of the most interesting to the physician, and at first most discouraging to the patient. The symptoms present are evidently due to the eye-strain, and yet after care-

ful and detailed examination of eyes, refraction, muscular equilibrium, etc., either nothing can be found wrong, or, after all errors are accurately corrected and have been shown by repeated examination to be accurately corrected, the symptoms persist or are aggravated by the glasses prescribed. Neither glasses nor mydriatics aid much in the elucidation of these cases; one thing only brings about their final solution, and that is the lapse of time. This shows that they are cases either of latent hypermetropia, latent astigmatism, or latent heterophoria. The significance of this is very great. It amounts to saying that while it may be possible to determine positively the existence of certain errors at the first examination, we are not justified even when the first tests are absolutely negative in saying that no error exists or that no error in addition to what we have discovered exists. We can never say "this patient's eyes are perfectly free from refractive or muscular error," until the lapse of a considerable period of time, and repeated examinations have taken place. In fact there is good reason to think that old age is reached before the complete manifestation of these errors in some people.

It is a common idea that atropin and other mydriatics produce a complete paralysis of the ciliary muscle, and thus reveal all the latent refractive error. There are many exceptions. Atropin of the strength of 4 grains to the ounce used three times a day for several days at a time may yet leave hypermetropia unrevealed, as the future history of the case may show.

Thus: H. S., aged eleven years, in February, 1894, accepted for each eye +0.25s.+0.25c. R. axis 105°. L. axis 75°. After atropin had been used for three days testing gave R.+1s.+0.25c. ax. 100°. L. 1.25s. 0.25c.ax. 80°.

In April, 1896, after using atropin for five days R. accepted +1.25s.+0.37c. ax. 105°. L.+1.5s. and c.+0.25c. ax. 75°.

In December of the same year, after using atropin five days, R. accepted +1.75s. and c. L.+2s. and c.

Five days more of atropin did not change the result. Thus, in 1896 nearly twice as much Hy. could be demonstrated as was shown after atropin two and one-half years earlier.

What is true of latent hypermetropia is also true of some cases of astigmatism. Although less common, latent astigmatism is nevertheless a reality, and occasionally in spite of the use of the usual mydriatic years have to elapse before the manifestation of the total astigmatism takes place. Until this occurs the relief afforded is incomplete or transient, or both. I have seen many instances of this condition, and report the following as a striking instance:

W. B. D., aged sixteen years, first seen on October 9, 1890. Symptoms: rapid tiring of eyes in reading. Examination showed astigmatism, +0.5Dcyl.; axes 90° in each eye. A mydriatic (homatropin) was used, and disclosed in addition to the astigmatism, which remained unchanged, 0.5D of hypermetropia. Tests of the muscular equilibrium showed also a tendency to convergence, corrected by a prism of 5°. He was given a correction for the astigmatism and 1½° prisms for each eye, and remained comfortable until April, 1891, when his asthenopia returned. Examination showed no change in the amount of astigmatism but an increase in convergence, and the prisms were increased to 3° each. This gave him sufficient relief to prevent my seeing him for three years, when he returned with asthenopia after one hour's reading. The ophthalmometer had in the meantime come into general use and it showed in each of his eyes a corneal astigmatism of 2D at 90°. Homatropin was again used and he accepted a +1D cyl. in each eye, or double what he had previously chosen, the hypermetropia remaining the same. Convergence was now 12°. The glasses prescribed upon this basis gave him relief until January, 1895, when the left eye accepted +1.25 cyl. In July, 1895, the right eye took +1.25c. and the left +1.5c., the convergence amounting to 15°.

As the indications were that the latent convergence was causing some of the symptoms, and as it was increasing in degree in spite of the fuller correction of the refractive errors, in the following September I corrected it by partial tenotomies, reducing it from 15° to between 2° and 3°. In November+1.75D. cyl. corrected the astigmatism in each eye most accurately and was prescribed. He got on well until June, 1896, when there was some return of the asthenopia, due to the latent convergence remaining uncorrected; this finally amounted to 9° and was corrected in January, 1897, leaving perfect equilibrium. He now has no trouble at all.

In this case a lapse of five years occurred before the astigmatism became completely manifest. He is now wearing cylindrical glasses just three and one-half times as strong as those originally accepted.

Another group of cases of exceeding interest are those in which there exists a latent deviating tendency of the visual axes at first and often for a long period of time incapable of demonstration.

For instance, a patient complains of rapid tiring of the eyes in near work, or headache, or some such symptom, and we find or satisfy ourselves that there is no error of refraction, or that such errors as exist are accurately corrected; we then investigate as the next most probable source of trouble, the extrinsic muscular system. We annul the binocular function by one of the many methods at our command, and we find the visual axes parallel and, perhaps, also the adduction and abduction and sursumduction within the normal limits. There is no indication whatever of faults of equilibrium.

There is nothing to be done in such cases except to prescribe such glasses as are necessary to correct the errors of refraction, if any, and wait for future developments. In some cases the manifestation of deviation may be aided and hastened by the systematic measuring of the different

pairs of muscles and prescribing of prisms to relieve those that are relatively weak, but, as a rule, the *lapse of time*, and sometimes a considerable period of it, is the only element which will bring about a final solution of the problem.

I now wish to detail two or three of these cases and I do so without any apology, for they are not only of great importance in themselves, very suggestive in their bearing on cases we see and do not understand, but there is good reason for thinking that the frequency of their occurrence is not widely appreciated.

The first case is that of Mrs. C. E. L., aged thirty-eight years, who was examined first on May 15, 1891. She had always been a great sufferer from sick headache, occurring about twice a week, accompanied by fearful nausea and severe vomiting. Other members of her family were also subject to the same affection. She had no difficulty in using her eyes. Examination showed that there was a moderate degree of astigmatism in the R. eye +0.75D cyl.: axis 75°. L. + 0.25 cyl. 120° and latent divergence 4°. The cylinders were prescribed.

In January, 1892, she reported herself no better. The R. accepted the same, and the L. was very indefinite in the choice of cylinders; therefore, as there remained a low degree of divergence, a prism base in 1″ was substituted for the L. cylinder. March 30, 1893, she was unimproved, having, in fact, sick headache commonly two or three times a week, the longest interval having been five weeks. She now showed divergence 7° and a 3° prism was placed before the L. eye. One week later a deviation of the right eye 1° higher than the left was demonstrated. This was the first time, although she had been under observation already for two years, that any tendency to deviation in the vertical direction could be detected. A prism 1° base down was ordered for R. eye. Three weeks later she returned with the report that she had had much less headache; examination now disclosed R. hyperphoria 2°. On July 18th the error measured 4-5°. She had had one headache only in the preceding three months and less insomnia. In December, 1893, she was prescribed R. + 0.75c. 75° pr. 3½° base down. L. 0.25c. 130° pr. 3° base in.

In September, 1894, she reported an interval of three months without a headache, but within past four weeks three attacks had occurred. The vertical deviation now measured 7° and the lateral 6-7°. As this was too much for convenient correction by prisms, tenotomy was advised but not accepted. In June, 1895, she reported no headache for four months.

In May, 1891, no error could be detected in the vertical plane; three years later the R. eye could be demonstrated to tend upwards to an extent requiring a 7° pr. for the correction (*i. e.*, 3½° actual deviation).

When it is remembered that the ordinary power of independent vertical movement is from 2° to 3°, the magnitude of this error can be better appreciated. The persistent innervation necessary to maintain parallelism of the visual axes resulting on the one hand in a very fixed spasm of the muscles innervated, and on the other hand in a state of neurasthenia, expressing itself by the frequent explosions constituting sick-headache.

The second case, F. T., aged twenty-three years, was first seen in May, 1894. His symptoms were headache with confusion in the head after reading, and some intolerance of light. Examination disclosed some mixed astigmatism in the left eye, the ophthalmometer showing a much higher degree of astigmatism than the glasses he accepted. The muscular equilibrium was normal.

I prescribed for him three times within three months without giving him any relief except for one week after the first prescription. I was entirely unable to demonstrate any fault in the balance of the ocular muscles. After the third prescription he disappeared. He went the rounds of all the oculists in the neighborhood and being apparently unable to get out of the vicious circle he reappeared in my office on September 9, 1897. He reported that he was better without than with the last glasses prescribed by me; that in the interval he had been prescribed an indefinite number of pairs of glasses, etc., without relief. His chief symptom now was intense photophobia. Examination showed a little less astigmatism than at his earlier tests, and also what had never given any indication of its presence before, a latent deviation of the L. higher than the R. of ½°. His refraction was carefully worked out, both without and with a mydriatic, the result being that glasses not very different from those originally prescribed were ordered, with the addition of ½° prism to offset the deviation. Some relief was at once experienced and more deviating tendency soon manifesting itself, was corrected by prisms, until on October 2d he reported himself much more comfortable and able to be out on the shady side of the street without colored glasses, whereas, two weeks before he could scarcely look out of doors with colored glasses.

With a fuller correction he reported on October 13th that he was able to be out in the sunlight for a short time without colored glasses, and had, in fact, worn none for five days. The total deviating tendency now equaled 2° and was fully corrected in the glasses prescribed.

The last case I have to report was even more perplexing and complicated than any of the preceding. It was under observation a little over four years, and during this period of time changes of three different kinds occurred in the eyes.

At the end of this period four times as much astigmatism could be demonstrated as at the beginning. From a moderate degree of hypermetropia the eyes changed to condition of moderate myopia. Whereas in the first place but little latent deviation, and that convergence, was shown, four years later a very considerable upward and inward deviation could be demonstrated.

This patient was fourteen years of age when I first saw him in 1899, and complained of defective vision and aching. He had been prescribed

+0.25 cyl. by one of the best-known men of Detroit, which relieved him until he went to school. Examination showed that he had a low degree of Hy. astigmatism in each eye, fairly accurately corrected by the glasses already prescribed, and also a convergence of 8°. Prisms 1½° base out gave him more relief than the previous glasses. Five months later (March, 1891) he returned with more asthenopia and more astigmatism could be detected +0.5 cyl. each. No latent convergence was to be found. Indeed, the muscular balance had become perfect.

In September, 1891, symptoms returned, due to apparent increase of astigmatism, which was corrected. In April, 1892, the R. preferred a concave cylinder. In September, 1892, the R showed less astigmatism than at either of the preceding visits.

Now, for the first time in one and one-half years a low degree of latent convergence could be detected, amounting to 2°. In April, 1893, he came back again with an increase of symptoms. On this date his eyes were examined with the ophthalmometer, which showed corneal astigmatism, R. 1.5D 90°. L. 1.75D 90°. He accepted stronger astigmatic glasses than before, the astigmatism being myopic in the right and mixed in the left eye. Esophoria, 1½-3°. A full correction of his astigmatism was prescribed. It aggravated his symptoms.

In August, 1893, no better; lacrimation, headache. Latent convergence of 4° could be demonstrated, and prisms 1½ each, correcting the greater part of this, relieved his symptoms. No hyperphoria. In January, 1894, return of symptoms, again relieved temporarily by correction of slight change in refraction. On July 17, 1894, tests showed the presence of a tendency of the right eye to deviate upward 1°. R. sursumduction, 2°. L. 1°. Let me emphasize the fact that he had been under observation more than three and one-half years before any hyperphoria could be detected. With the temporary use of a prism the deviation increased to 1½° and prisms correcting that error were introduced into his glasses. The final tests were made in December, 1894, on three or four consecutive days, and resulted in showing myopic astigmatism in both eyes, hyperphoria of 2°, and latent convergence of from 2° to 8°. The glasses ordered on this basis having given him practically complete relief. R.—0.75c. 170° pr. 2° base out-down pr. axis 40°. L.1c. +0.25s. pr. 2° base out-up pr. axis 40.

I have very little to add by way of comment to these cases. It seems to me that the facts they contain fully justify the statement made earlier in the paper that it is impossible at an early stage of investigation to disprove the existence of certain efficient causes of asthenopia and that time alone can be depended upon to solve the problem.

If I have succeeded in showing that, at any rate in some cases, legitimate excuses may be made for the ophthalmologist who fails to relieve asthenopia promptly, the object with which I prepared this paper has been attained.

LATENT INFECTION AND SUBINFECTION AND THE ETIOLOGY OF HEMOCHROMATOSIS AND PERNICIOUS ANEMIA.[1]

BY J. GEORGE ADAMI, A.M., M.D.,
OF MONTREAL;
PROFESSOR OF PATHOLOGY MCGILL UNIVERSITY.

FACTS are not of necessity truths; however sure we may be at a given moment of the facts upon which we base our conclusions and determine our treatment, those facts may not be the whole facts, those truths not the whole truths. Aseptic and antiseptic surgery, and our theories with regard to infection, have for years been based upon a fundamental postulate that the skin and the mucous surfaces of the body form a natural barrier beyond which, under normal conditions, bacteria do not pass; that the presence of bacteria in the deeper tissues is the exception and not the rule. While it would be absurd to deny that this postulate has been the most valuable, for without it modern medicine could not be in its present position, and while admitting that if not true it must be somewhere near the truth (otherwise facts and observations would not conform to it in so great a measure), is it the whole truth, does everything prove that, normally, the tissues are free from bacteria?

Studying more especially the digestive tract, the observations of Schæfer, Zawarykin, Heidenhain, and A. B. Macallum show that constantly, more especially during the digestive act, leucocytes containing various materials pass out into the lumen of the intestine and pass back again into the submucous tissues, into the lymphatics of the villi, and into the portal venules also present there. Among these, as shown very clearly by Ruffer's observations, are bacteria. If the small intestine of the healthy rabbit be taken immediately after death, sections being cut and stained by the ordinary methods, abundant leucocytes containing micro-organisms are found in the lymph-follicles of the Peyer's patches; the same is true also in connection with the tonsil. Bacteria so passing in tend to be destroyed and the lymph-glands in the subepithelial and submucous areas of the respiratory system may be regarded as a second line of defence of the organism against bacterial invasion.

But these facts show that at least one tissue, if not normally sterile, may be regarded as *potentially sterile;* the tendency is for entering bacteria to be rapidly destroyed, but it is possible to realize conditions under which this destruction is not adequate. We can, however, go beyond the submucous glands. Dr. A. G. Nicholls, Senior Demonstrator in Pathology at Magill University, has recently pointed out that if the mesentery and the small intestines of healthy rabbits be properly removed immediately after death and properly stained, the mesentery shows relatively abundant bacteria within it in various stages of disintegration. The same is true not only of the lymph-

[1] Abstract, made by the author, of an address delivered before the Society of Internal Medicine, Chicago, Nov. 29, 1889.

oid tissue but of the mesenteric glands. My own observations have carried this subject of the existence of bacteria in the healthy tissues a considerable step further. It has been repeatedly demonstrated that within a very few minutes after intravenous inoculation of bacteria (*e. g.*, anthrax and tubercle) these are taken up by the endothelial cells of various organs, more especially the liver. In the studies made by Drs. Adami, Abbott, and Nicholson, they found that taking the colon bacillus and inoculating this intravenously, within a quarter of an hour the endothelial cells of the liver showed abundant contained bacteria, which were undergoing degenerative changes. The long rods tended to break up into short pieces and in several cases all that could be seen of them were small diplococcoid-like bodies still staining strongly but absolutely unlike the original bacillary form which had been inoculated. At a still later period, in from two to four hours, an increased number of minute slightly brownish diplococcoid forms were made out actually within the liver-cells. The same process also occurred in the cells of the convoluted tubules. These bodies vary considerably in their size and are evidently in various stages of destruction and dissolution, and they can only be recognized by the higher powers of the microscope; the ordinary one-twelfth immersion is generally insufficient to demonstrate them properly. It was pointed out that these could only be the remains of the inoculated bacteria.

Long ago Cohnheim suggested that the body protects itself by excreting living germs through the liver and the kidney. The observations of Wyssokowitsch appear to definitely disprove this, and Sherrington came to similar conclusions altogether, although he pointed out that occasionally he found bacteria in the urine and bile without blood being present or any evidence of actual gross lesion in the tissues.

Among those who have confuted Wyssokowitsch's observations, the studies of Dr. Fütterer of Chicago are more especially noteworthy. This observer was able to find the bacillus prodigiosus in the pelvis of the kidney of a dog two minutes after injecting a culture into the jugular vein, and he obtained the same micro-organism and the pyococcus aureus from the common bile-duct within three minutes after he had inoculated them into the blood of the left side of the heart. He therefore concludes that certain bacteria at least are actually excreted as Cohnheim suggested. So also in personal experiments with the colon bacillus the minute and apparently dead diplococcoid forms in the bile have at times been found, but their very appearance indicated that they had been acted on during their transit through the liver. When the number is not too great the liver tissue is capable of wholly destroying and digesting bacteria circulating in the portal blood. Where, however, this function of the liver-cells becomes exhausted by the taking up of excessive numbers of the bacteria, then it is possible for these to be excreted in the bile in a still living state.

These observations appear to demonstrate clearly that while one of the functions of the lymphatic gland is to take up and destroy bacteria gaining an entrance into the lymph, a function of the liver, both as regards its endothelium and its cells, is to take up and destroy such bacteria as are introduced by leucocytes into the venules of the portal system, while similarly a function of the kidney parenchyma, more especially of the convoluted tabules, is to remove bacteria circulating in the systemic circulation.

Not only can these powers be shown experimentally, but in the liver-cells of normal animals, of man and of the rabbit for instance, the brownish diplococcoid bodies which would seem to represent not necessarily only the degenerated colon but it may be other bacterial forms are normally present, while inflammation of the intestines, judging from the great numbers present in sections of the liver after such, would seem to favor the passage of bacteria into the portal blood.

These views, it is true, appear to be diametrically opposed to the very numerous observations that have been made upon the bacteriology of the normal blood and of blood in cases of disease and in the bacteriology of normal tissue. While it was generally held that normal blood is absolutely sterile, the observations of Nocard, confirmed by Porchard and Désoubry show that, more especially after a meal, bacteria are present in the chyle and cultures may be obtained from the normal blood. These observations of Nocard have been given the lie direct by Max Neisser and others. Making cultures from the chyle, the lymphatic glands, etc., this last observer came to the conclution that the chyle is absolutely free from germs, as is also the normal blood. Recently Franklin Warren White of Boston, studying the blood in various diseases, obtained from 92 cases of active disease only 12 cultures from the blood; all of these were staphylococci, streptococci, and pneumococci. Warren White himself has in conformity with other observers shown that the blood-serum even of healthy individuals is not markedly germicidal for pus-organisms. In this lies the explanation of the whole matter. The observers who have most frequently gained positive results are those who have employed broth cultures and have diluted the blood considerably, whereas those who have worked by means of streak and plate cultures of solid media have gained positive results with forms which are relatively resistent to the germicidal action of the blood-serum. These observers have failed to take into account the strong bactericidal action of the shed blood; 1 c.c. of shed blood will kill thousands of anthrax bacilli, for example; a very much smaller number introduced into the total circulating blood of the rabbit will proliferate and cause the death of the animal; the bacterial powers of the circulating blood are relatively slight, whereas those of the shed blood are remarkably powerful. It is in the act of coagulation that the bactericidal substances are for the greater part liberated. There is little wonder, then, that in the observations of White,

Petruschky, Sittman, Neisser, etc., only those forms and just those forms relatively resistent to the bactericidal action of the blood-serum managed to proliferate and to form colonies. In short, the only method to determine the presence of bacteria in the circulation blood with any accuracy is one which until now has been little employed; it is that of diluting the blood with 100 or 200 parts, or more, of broth whereby the bactericidal substances are so diluted that bacteria may grow.

Similar considerations and similar criticisms may be brought to bear upon the observations which have been made with reference to the existence of bacteria in the normal tissues. Time and again observers like Hauser, Neisser, and others have found that the tissues of healthy animals are so frequently sterile that the occasional gaining of cultures from the organs has been referred by them to contamination in the admittedly difficult task of removal of organs or parts of organs from the body into sterile receptacles. Thus, for example, Neisser out of some 37 rabbits, mice, and guinea-pigs, which he fed with various pathogenic and non-pathogenic organisms, and in certain of which he further set up grave intestinal irritation by giving at the same time croton oil or powdered glass, failed to gain cultures from growths in the liver, spleen, kidneys, lungs, etc., in 24, and only gained cultures, and these in not all the organs, in the remaining 13. His method apparently was the most complete. The animals were skinned, then placed in sublimate solution so as to sterilize the surface, and then fastened out upon sterile boards. The operator, having his hands sterilized, removed each organ in turn with a separate set of sterile instruments, and then placed it in a sterile vessel. Melted gelatin or, rarely, melted agar was then poured over them and only after two days were they examined.

The results seem most positive and what is remarkable is the fact that even when cultures did grow in the organs in general, they were not the identical forms with which the animals had been fed.

Recently, Dr. A. G. Nicholls and Dr. Ford, Fellows in Pathology at McGill University, have been repeating these observations, and it must be confessed that very different results have been obtained, and it has been discovered wherein Neisser was led astray. The animals employed by Dr. Ford have been rabbits, and he has taken precautions similar to those employed by Neisser to guard against contamination. The organ or part has then been dropped into a sterilized bottle containing melted gelatin or melted agar, so that if there were any subsequent contamination by the air it would first of all show itself upon the surface of this solidified medium. Dr. Ford will, of course, publish his whole series of observations later, but he has done sufficient to allow the statement that where organs *immediately after death* are placed in gelatin and kept in the cold, a large proportion remain absolutely sterile and show no growth, whereas when placed in agar and kept at the body temperature, the majority of livers and kidneys show relatively abundant growth after two days or less.

Here again the bactericidal influence of the body tissues come in. It may be that in the organs not immediately removed after death such bacteria as are present undergo attenuation and destruction with fair rapidity, unless, as in cases of disease, they be present in relatively large numbers while at the same time the bactericidal powers of the tissues are depressed. What appears more evident, however, from Dr. Ford's results is that this inhibitory action of the body tissues upon microbes that are accustomed to live at the body temperature is favored by keeping in the cool, or more correctly, that the activity of the growth of the bacteria is depressed.

Before proceeding farther the conclusions which may be legitimately adduced from the facts so far brought forward seem to be the following:

1. Normally there is a passage of leucocytes through the mucosæ on to the free surface of, more especially, the alimentary tract.

2. That these leucocytes while in part undergoing a destruction, in part find their way back between the epithelial cells, bearing with them foodstuffs and solid particles among which may be the bacteria present in the cavity of the gut.

3. That during the active congestion which accompanies digestion the passage out and return of these wandering cells is increased.

4. These cells upon their return find their way either into the lymphatic channels or the venules of the portal system.

5. That in either position they tend to be destroyed and digested by the leucocytes and thus, while preparations of the mesentery and of the mesenteric lymphatic glands may show abundant bacteria, the vast majority of these at the same time show obvious degeneration, while cultures made from the mesentery or from the lymphatic glands on ordinary media by ordinary methods as a consequence tend to remain sterile. Similarly in the normal liver the same rapid destruction takes place so that here again by ordinary methods no evidence of living bacteria is obtainable.

6. By the employment of adequate methods it can be demonstrated that even in the healthy liver and kidney in a large number of cases, in one animal at least (the rabbit), a certain number of living microbes are present at any one moment, so that if the healthy organ be removed from the body cultures of these living microbes can be obtained.

7. It is most probable further that in ordinary health a certain number of bacteria which have not been destroyed by the leucocytes or removed by the lymphatic glands or endothelium of the portal system, pass either through the thoracic duct or through the liver into the systemic blood. Such bacteria tend to be removed more especially by the kidneys, although it may be by other glandular organs. In any case the ordinary methods at present employed in making cultures from blood are inadequate to detect the presence of such bac-

teria unless they are of such a nature or are circulating in such quantities that the whole number is not destroyed by the bactericidal action of the shed blood.

It follows further from these conclusions that there does exist a condition of what the French term latent microbism, or what should be more correctly termed for practical purposes *latent infection*. We have abundant evidence that even in the healthy feces such forms as the pyococci, streptococci, and the bacillus pyocyaneus, are to be encountered fairly often. We know further that the commonest form inhabiting the intestine, that which outgrows all other forms, namely the colon bacillus, even when obtained from perfectly healthy feces may show marked pathogenic properties when inoculated into the lower animals.

We know further as a common fact in pathology that, just as one swallow does not make a summer, an isolated microbe gaining entrance into the system does not usually set up disease. Save when we are dealing with the most virulent forms of pathogenic micro-organisms and with animals which are peculiarly susceptible, it requires numerous bacteria entering at the same time to so lower the resisting powers of the tissues as to thus survive and proliferate. If therefore in the intestine, here and there at scattered points, individual bacteria are being introduced into the system from time to time, that does not necessitate proliferation and consequent infection. But, on the other hand, we can equally well understand that if from some cause or other, as, for example, by inflammation along the intestinal tract, whereby excessive numbers of bacteria are introduced, or, again, in conditions such as are afforded towards the conclusion of long continued chronic wasting disease, the reactive powers of the tissues are greatly lowered, then everything favors the multiplication of bacteria so introduced and the development of either localized —so-called cryptogenetic infection—or of general septicemic disturbances.

The observations of Flexner ("Exper. Med.," Vol. 1, No. 3, 1896) upon terminal infection show in the most vivid light how common it is to have death preceded by such general or local infection by germs totally foreign to the main morbid condition, and amply confirm Osler's paradox that "persons rarely die of the disease with which they suffer" ("Practice of Medicine," p. 132, 1895).

If we accept the conclusions above mentioned we gain a more correct understanding of "post-mortem infection" of the body. The usual explanation of the abundant growth of bacteria in the various organs after death is that, while there may be an agonal invasion of bacteria, the essential cause of such infection and subsequent putrefaction is the entry of bacteria, more especially through the intestines, after death. Birch-Hirschfeld has recently reaffirmed this and has brought forward certain observations of his own in favor of such a conclusion. It is an interesting point that Birch-Hirschfeld in this supposed invasion admits that the various organs show no particular sequence of infection as again that morbid changes appear in the intestine to have no influence on the time of appearance of the bacillus coli communis in the internal organs. It is most interesting further to observe that the period of ten hours mentioned by him corresponds singularly with the period mentioned by Flexner at which the blood of the cadaver loses its bactericidal function, and, lastly, it is of importance to notice that those who have explained the post-mortem infection by this method have never demonstrated what ought to be on this view most clearly demonstrable, namely, the existence of masses of bacteria in special abundance in the intestinal wall and appearing to be growing through that wall into the blood-vessels and surrounding tissues.

It is impossible from the above observations to come to any other conclusion than that at the moment of death, or shortly before, the lowering of the vitality of the tissues permits a larger number of bacteria than normal to be present in the living state in the blood and lymph. Just as when one removes the blood or takes the tissue juices outside the body and adds to certain quantities of these fluids a fair number of bacteria, the tendency is for certain of those bacteria to be destroyed during the first few hours, then gradually for the remainder to multiply; so in the dead body there would seem to be often, but not always, a preliminary period in which the bactericidal action of the tissues continues and the number of bacteria to be obtained from the tissues by ordinary methods is singularly small; following upon this there is multiplication.

But apart from this latent infection and the sudden and acute infection to which it may at times give rise, if we admit this normal passage in and normal destruction of bacteria by the tissues, there would seem possible an intermediate condition which may be termed *subinfection*, a condition of chronic inflammatory disturbance in which as a consequence—in connection with the gastro-intestinal tract—there may for long periods pass in through the walls of the stomach or of the intestine a greater number of ordinary bacteria inhabiting the tract, and while these bacteria undergo the normal and inevitable destruction by the cells of the lymph-glands, the liver, the kidney and other organs. The excessive action of these cells and the effect upon them of the bacterial toxins liberated in the process of destruction may nevertheless eventually lead to grave changes in these cells and in the organs of which they are part; changes which are of a chronic nature. At no individual moment may we find evidence of the presence of large numbers of living bacteria in such organs, but we may find the evidence of their presence in the cells and may find certain chronic inflammations associated with or the result of this overwork of the bacteria destroying cells. It is possible that there may exist a morbid condition, the existence of which has not so far been fully recognized. The absolute recognition and determination of this condition is ren-

dered peculiarly difficult by the fact that any chronic catarrhal or inflammatory condition of the intestines is accompanied by abnormal fermentative changes in the intestine. And thus at the present time it is almost impossible to distinguish and divide conditions which might be due to this combined cell exhaustion and cell intoxication from the intoxication and the disturbances due to increased absorption of soluble poisonous products through the intestinal wall.

Certain observations that I have been making during the last two years lead me to believe in the possibility of such a condition as subinfection. In the first place these minute diplococcoid bodies are to be found peculiarly frequent in the liver cells in cases of hepatic cirrhosis, and, since finding these, the more I have myself made autopsies in cases of this condition and the more I have studied carefully the records of others, the more it has been brought home to me that accompanying ordinary progressive cirrhosis there is a chronic catarrhal condition of the intestines together with a definite enlargement of the retroperitoneal and mesenteric lymphatic glands. Here it is more especially in the cells at the periphery of the lobule that the presence of these bodies is noticeable; in those cells, that is to say, which are first fed from the blood coming from the portal vessels and which again are most liable to undergo atrophy and to be affected by the fibroid change occurring in the interstitial tissues.

The first view, that these little bodies were directly associated with cirrhosis and indicated a specific micro-organism, was rapidly modified by the discovery that cultures from the cirrhotic livers and from the bile in such cases, while at first tending to give a form of diplococcus, subsequent culture and passage through animals developed into a form morphologically unrecognizable from the colon bacillus, while frequently absolutely typical colon bacilli were obtained from these organs and from the rest of the body.

Later there has come a case of well-marked hepatic cirrhosis associated with great pigmentation of the skin and the intense development of the condition known as hemochromatosis. Here in this case, as in other cases of hemochromatosis, there was iron-containing pigment in the liver, the mesenteric glands, the pancreas, and to a less extent in the spleen, kidneys and the heart. What the cause of this hemochromatosis is has been a matter of very considerable conjecture of late years. A very full paper on the subject is to be found in the *Journal of Experimental Medicine* by Dr. Opie of Baltimore. In this he comes to the conclusion that the condition is a distinct morbid entity characterized by the widespread deposition of the iron-containing pigment in certain cells and the association of iron-free pigment in a variety of localities in which pigment is found in moderate amount under physiological conditions. With the pigment accumulation there is degeneration and death of the containing cells and consequent interstitial inflammation, notably of the liver and pancreas which become the seat of inflammatory changes accompanied by hypertrophy; while when the chronic interstitial pancreatitis has reached a certain grade of intensity diabetes ensues and is the terminal event in the disease.

Dr. Mause E. Abbott, who has been working at the Royal Victoria Hospital on this subject for some months, has reached somewhat different conclusions. He finds that this deposit of the iron-containing pigment is not necessarily the morbid entity which Opie would make it out to be. Dr. Abbott's material has been carefuly gone over, and to my astonishment it was found that where this pigment is not clumped together into too large masses, in the liver cells, for example, as again in the abdominal lymphatic glands, a very large proportion of the ultimate fine masses of pigment, reacting to Perl's test and containing iron, are distinct diplococcoid forms or bodies. Of this there can be no doubt. In short the condition of hemochromatosis is of bacterial origin, and just as Hintze and, even before him, von Recklinghausen pointed out, the slightest case of hemochromatosis presents itself merely as a brownish coloring of the abdominal walls. Here we may have a succession of cases in which at first only the abdominal walls and the mesenteric glands become the seat of the deposit of this pigment and to a slight extent the liver, then cases in which the liver is seriously involved with associated or accompanying cirrhosis, and in still others in which the pancreas also becomes the seat of this abundant deposit in the cells of minute pigmented granules which are the modified "corpses" of bacteria.

The appearance of these livers of hemochromatosis is of the same nature as that seen in pernicious anemia, and examining sections from pernicious anemia livers the same minute ovoid and diplococcoid bodies are seen in the liver cells. In short, in pernicious anemia pigmented granules are not merely, as has been thought up to now, a modified substance obtained by the disintegration of red blood-corpuscles, but are the evidence of such a condition of subinfection as that above referred to—the chronic inflammatory condition in the upper digestive tract being associated with excessive passing into the portal blood of colon and allied bacilli which subsequently take up iron-containing pigment from destroyed red corpuscles.

ASEPTIC CATHETERISM.

By CARL BECK, M.D.,
OF NEW YORK.

CATHETERISM is the most important procedure in the treatment of the genito-urinary tract. As it has the dignity of a surgical operation, it should be viewed from a strictly surgical standpoint and should especially be preceded by the same preliminary precautions, at least in principle. These precautions consist in the sterilization of the instruments, the hands of the surgeon and the field of operation.

As far as the first point, the instruments, in this instance the catheter, is concerned, it can safely be maintained that ideal asepsis has become an established fact, because all objects which stand boiling well can be rendered aseptic in boiling water; a means accessible everywhere. There is no more excuse for a surgeon to claim that "the poor circumstances of the patient's surroundings did not permit of aseptic precautions." Water, fire, and boiling-pot can be obtained in the poorest hut, so that not only instruments but also dressing-material, etc., can be sterilized. The hands of the surgeon should be thoroughly cleaned by mechanical means, *viz.*, scrubbing with soap and hot water. The sterile sand-soap mixture, advised by me, can also be used instead of a brush for scrubbing. Attention must be given to the folds and creases of the skin and the subungual spaces. The latter require the use of a nail-cleaner and energetic wiping with the soap. The skin is then dried with a clean towel and rubbed for about one minute with a gauze compress, saturated with fifty per cent. alcohol. The alcohol is used mainly for the purpose of dissolving the fat of the skin which shelters the bacteria; and by dissolving the shelter, the bacteria are removed at the same time. Whether washing with bichlorid of mercury is needed after these procedures is open to discussion; it will certainly not do any harm. With reference to the third point, the field of operation, we may safely say that if particular attention has been given to the balanopreputial space, that hotbed of different bacterial species, especially the bacterium coli commune, the introduction of bacteria *into* the urethra is surely prevented, provided the instruments and hands of the surgeon were sterilized as described above. The analogue to the balanopreputial space in man is the vulva in woman.

The great stumbling block, however, of thorough asepsis is represented by the fact that even the normal urethra contains numerous bacterial species, some of which unfortunately are pathogenic. Melchior found staphylococci as well as streptococci eight times in twelve cases in normal urethras. It is obvious that in a diseased urethra, and whenever catheterism is considered the urethra is generally in a pathologic state, the number, the virulence, and the varieties of bacteria are increased. While it is simply a matter of conscience whether the introduction of bacteria from without is prevented or not, it is utterly impossible to destroy intra-urethral bacteria. It is claimed that by the injection of one or another antiseptic drug with one or another perfect apparatus these bacteria can be destroyed. It is amazing to find such statements made by surgeons who would ridicule a prophylactic disinfecting process, attempted on the outer surface of the body, which would simply consist in irrigating the field of operation with a mild antiseptic. The modern surgeon is contented only after scrubbing with soap and water and subsequent application of alcohol and bichlorid of mercury or a similar antiseptic. And even then there is another surreptitious enemy of asepsis, intracutaneous bacteria, which should not be underrated. These cannot be reached by any disinfecting process. They are set free as soon as there is an injury of the integument, and it is only by protecting the skin margins of the wound with sterile compresses, after the skin is dissected, that they can be kept in check.

No precaution of this kind, however, can be taken in the urethra, which, moreover, is a much more congenial resting place for bacteria than the skin surface of the body. In the first place, scrubbing with soap and water and wiping with alcohol and bichlorid of mercury or similar procedures are out of question, and as far as antiseptic drugs are concerned, we can only resort to the mildest, since strong solutions would not be borne by the mucous membrane of the urethra. So it can hardly be expected that by simple irrigation of a mild antiseptic, the intra-urethral bacteria can be destroyed. And if there is an injury, be it caused by a cutting instrument or by the friction of a catheter, not only bacteria of the intra-urethral surface but also those sheltered by the follicles have a good opportunity to infect the adjacent tissues. This finds its simple clinical illustration in the fact that whenever blood shows after catheterization there will be a chill, the injuring instrument having opened an avenue for infection. So we see that thorough prophylactic disinfection of the urethra is still a pious wish. This, however, should not encourage any sins of omission. There are surely several points the observation of which will lessen the chances of infection. In the first place irrigation of the surface of the mucous membrane of the urethra will remove a certain number of bacteria. A much more important point is to avoid even the slightest injury while introducing a catheter. Any slight amount of friction may cause an abrasion and thereby open a way for infection. Force must therefore never be used during catheterism. The instrument always tells distinctly how far the surgeon may go, but it is necessary that its language be understood by the surgeon. Bearing in mind the fact that the bacteria in the lacunæ and follicles are set free by dissection, extensive intra urethral operation should be omitted whenever other means can be found to obtain the desired effect.

A third point is that, being unable to rely upon our usual aseptic methods, we should resort to those antiseptic principles which are applicable to the urethra. In other words, as our active antiseptic drugs, like bichlorid of mercury, etc., cannot display their valuable properties as fully in the urethra, we would better rely on a passive bacterial destroyer, like iodoform, which, while powerless where there is no injury, displays its unequalled properties in the presence of a lesion. Therefore I advocate the prophylactic injection of a five per cent. emulsion of iodoform in glycerin before the introduction of an instrument in the urethra. If an abrasion is caused, the iodoform will come in contact with the wound at the very moment it is made, and with the wound-serum at

its *stadium nascendi*. Iodin is set free, and during this chemical process bacteria are destroyed or their development at least is arrested.

Thus we see there are three most important virtues required in catheterism: Thorough cleanliness, extreme delicacy, and much patience. The same principles should be upheld if the patients are instructed to catheterize themselves. From a scientific standpoint, the trusting of such a surgical procedure to a layman is to be deplored, and such risky commissions should be resorted to only under the most pressing circumstances. Soft catheters should be chosen, and the fact that their usefulness is soon destroyed by repeated boiling should not be allowed to carry much weight in such a serious consideration.

CLINICAL LECTURE.

A SERIES OF CASES OF PISTOL-SHOT WOUNDS OF THE HEAD.

By CHARLES PHELPS, M.D.,
of New York.

The following cases of pistol-shot wound of the head, nine in number, have occurred in my service in two hospitals during the last two years:

Case I.—Ambulance history: Bullet of 0.38 caliber entered the head just in front of the right ear, and made its exit in the left anterior parietal region. The wound of entrance was lacerated and one inch in length; the wound of exit was lacerated and measured one-half by one-fourth-inch in diameter; brain matter was extruded from both wounds; consciousness was primarily and permanently lost. The right pupil was dilated, the left contracted, and the corneal reflexes abolished. On admission to the hospital, thirty-five minutes after injury, the patient was still in a condition of general shock; the skin was cold and moist, pulse 120, respiration 20, and temperature 101.6° F. The right pupil was still dilated, and the left less contracted. The respiratory movements became slower and of the Cheyne-Stokes character, edema of the lungs developed and death occurred in fifty minutes.

The primary symptoms in this case can only be attributed to general cerebral contusion, and those which immediately preceded death were due to hemorrhage into the occipital basal fossæ compressing the medulla and pneumogastric nerve.

Case II.—Ambulance history: Bullet of 0.38 caliber, fired from a revolver of foreign make, entered head one and one-half inches above and one-half inch in front of the right ear. There was free hemorrhage from the left ear and from both nostrils. No cutaneous exit. Loss of consciousness was complete, and death occurred before the patient reached the hospital.

Necropsy.—Cutaneous lesions: The hair, which was short, curly, and moderately thick, was burned down to the scalp around the wound in an area of one and one-half inches. The skin was charred over an area of three-fourths of one inch, and symmetrically scorced just at the margin of the wound except inferiorly, where the scorch extended three-fourths of one inch beyond the charred area; there were no free grains upon the surface, and none embedded, and no smoke deposit beyond the hair. The cutaneous wound was one-eighth of an inch in diameter. Subcutaneous lesions: The bullet track was blackened and contained free grains of powder; there was no other staining of the tissues or laceration, and no separation of the layers of the scalp. Osseous lesions: The osteal wound was irregularly circular and one inch in diameter; the eroded margin of the internal table of bones was powder-stained. Intracranial lesions: The bullet penetrated the brain immediately above the fissure of Sylvius in its middle portion, emerged through the superior surface of the left frontal lobe, lacerated the dura mater, and comminuted the left frontal bone just anterior to the coronal suture and one inch to the left of the median line. The bullet was then deflected downward and backward, traversing the left lateral ventricle, and was stopped in the median line above the cerebellum. There was no powder-stain of the dura mater, and but few powder-grains in the cerebral track of the bullet. There was little intracranial hemorrhage.

Case III.—Ambulance history: Bullet of 0.38 caliber, Smith & Wesson, fired from a cheap pistol, entered the head two inches above and one inch behind the right external angular process of the frontal bone and made its exit at a point near the center of the left frontal region without having penetrated the bone. The patient was pulseless and unconscious. On admission to the hospital consciousness had been regained, temperature was 99.4° F., and there were no general symptoms. The wound of entrance was circular, one-fourth of one inch in diameter, clean cut, and its edge was not burned; the hair was scorched in an elliptical area of two and one-half inches in its long diameter; the skin was scorched in an area of one by one and one-half inches, and powder-grains were embedded with traces of smoke in an area of one inch. The subcutaneous track of the bullet was found after the wounds of entrance and exit had been connected by incision to be powder-stained and the external table of bone to be depressed in a circular area of one-eighth of one inch in diameter with a fine semi-circular fissure above it. On the second day the patient became actively delirious; on the third day the temperature rose from 101° F. to 104.6° F., and rectal and vesical control was lost. The pupils were normal, and the delirium was thought to be of alcoholic origin. On the fourth day the mental condition became clearer and the temperature was reduced to 101° F. On the fifth day the temperature rose to 104° F. The pupils were somewhat contracted. There was alternate stupor and delirium, and there were muscular twitchings and picking at the bed-clothes, with continued loss of control over the feces and urine. On the sixth and seventh days the pulse was weaker and more frequent, and the temperature

varied from 103° to 105.6° F. On the eighth day the patient died in coma with a temperature of 106° F.

Necropsy.—Cutaneous lesions had disappeared. The osseous lesions were confined to external table; skull at site of injury three-sixteenths of an inch in thickness; no increase in subarachnoid fluid; trivial cortical hemorrhage upon surface of third right frontal convolution posteriorly derived from minute laceration at that point; pial hemorrhage over posterior part of right occipital lobe; general edema of brain substance with marked hyperemia of both occipital lobes and of right basal ganglia.

This case is one of the admitted exceptions to a general rule which has been formulated, that a pistol ball never causes a simple fracture and rarely a compound fracture, which is more than nominal unless the bone is also penetrated.[1]

This pistol-shot injury was attended by a fatal result and obvious intracranial lesions were disclosed. Death resulted from cerebral hyperemia and edema, the cerebral laceration and hemorrhage having been too insignificant to have occasioned symptoms; but while the pial hemorrhage and the localization of hyperemia in certain regions of the brain indicated the effects of traumatism, the patient's history and his early symptoms indicated also the influence of alcoholism. Whether the cerebral contusion would have proved fatal had the circulatory conditions not already been disturbed may be open to question. If, however, as it may well have been, the impact of the ball although causing so little osseous injury was solely or essentially responsible for the cerebral lesions this case is not only exceptional but remarkable.

Case IV.—Bullet of 0.38 caliber entered the head one inch behind and a little above the right external angular process of the frontal bone and was lodged in the subcutaneous tissue of the left upper eyelid; it was removed by incision. There was said to have been profuse hemorrhage from the nose, subconjunctival hemorrhage in both eyes, and ecchymosis of both orbital regions. It was also said that there were no general symptoms then or immediately afterward. The patient was admitted to Bellevue Hospital one month later and was then rational. Vision in the left eye was lost, and was limited in the right; temperature 99° F. On the morning of the following day a severe chill lasting twenty minutes was followed by a temperature of 103° F., which in twelve hours rose to 105° F. On the following day the condition of stupor lapsed into coma, which continued until death, which occurred on the fifth day. The urine was retained except on the second day, when there was loss of bladder control. On the last day there were general convulsive movements. The temperature after the day of invasion was of lower range. On the third day it was from 102.6° F. to 103.8° F., on the fourth day from 100.6° F. to 102° F.; and on the fifth day from 100.6° F. to 102.8° F.

[1] Phelps, "Injuries of the Brain," pt. II., pp. 335-336.

Necropsy.—The bullet passed through the upper part of the right orbit, and nasal fossæ into the left orbit, fracturing the orbital roofs without perforating the orbital periosteum, but driving spiculæ of bone into the inferior portion of both frontal lobes. Areas of purulent infiltration were scattered through the left orbit.

The dura mater was congested, thickened, and adherent to the pia mater. A layer of creamy yellow pus covered the entire surface of the brain, extended into the spinal canal, and was very abundant over the medulla and inferior surface of the cerebellum. The pia mater was closely adherent to the cerebral cortex in various parts. The cortical tissues were soft and edematous.

Bacteriological cultures afforded a mixed growth of the diplococcus intracellulosis meningitidis, of the bacillus coli communis, and of a short thick bacillus positive to Gram's stain not yet identified. (Brooks.)

Case V.—Bullet of 0.32 caliber entered the head one inch behind and one-half inch above the right external angular process of the frontal bone; no exit; hair scorched in area of one and one-half inches diameter, and skin in area of one inch; powder grains embedded in area of one-half inch; and smoke stain thick in an irregular area of approximately two inches diameter below and behind the wound.

Primary symptoms: Temperature 98 F., pulse 76, respiration slow and shallow; patient conscious but apathetic; pupils contracted and only slightly reacting to light; vision in right eye diminished; urinary control retained; no muscular symptoms. There was hemorrhage from the right nostril; blood and brain matter escaping from the wound. Fragments of the internal table of bone were removed, and the probe easily followed the ball track to a point near the left orbital plate. The wound healed at once without suppuration.

Later symptoms: There were no general symptoms aside from an abnormal mental condition until the twenty-fourth day, when the patient became unconscious. He was always apathetic and when sufficiently roused to make answer to questions was incoherent and his power of comprehension was deficient. Nourishment was given with great difficulty. Vesical and rectal control was lost with consciousness; at about the same time the lower extremities became rigid and their reflexes exaggerated. Death occurred on the thirty-first day.

The temperature until the eighteenth day ranged from 98° F. to 100° F., except on the fourth and fifth days, when it rose to 103° F., and on the eleventh day, when it rose from 98° F. to 104° F. From the eighteenth to the thirty-first days it ranged from 102° F. to 106.2° F. The pulse was ordinarily from 40 to 60, and only exceeded 100 towards the close of life.

Necropsy.—There was no epidural hemorrhage; the dura mater was adherent and there was a diffused subarachnoid seropurulent effusion. The crista galli was broken off. Upon

section the anterior half of the left frontal and anterior third of the right frontal lobe were each found to contain a large area of thick, creamy material, including fragments of bone and lead. A cylindrical area of softened material one-half inch in diameter extended from the disintegrated portion of the left frontal lobe through the left lateral ventricle to the postero-inferior part of the left occipital lobe, at the termination of which the bullet was lodged one-half inch below the surface. Small particles of bone and lead and a few grains of powder were found in the left frontal lobe outside the area of disintegration. The frontal sinuses communicated with the cranial cavity and contained a seropurulent fluid.

These last two cases exemplify the special danger from fractures involving the anterior fossæ of the cranial base. It is practically impossible to guard against infection through the throat and nose. In both of these cases septic arachnitis supervened; in Case IV. the path of infection must have been either through the orbital periosteum or through the ethmoidal cells; in Case V., although it might have led through the frontal wound, the late invasion of the disease makes it more probable that it was through the frontal sinuses in which a suppurative process was found to exist in continuity with that of the cranial cavity. In Case V. the predominance of mental symptoms during the time consciousness was retained was quite in accordance with what the writer has noted as characteristic of lesion of the left frontal lobe. The contention made in the work upon "Brain Injuries," previously quoted, that laceration of that lobe, either with or without laceration of the right lobe, occasions mental aberration or decadence, which is absent when the right lobe alone is injured, has since been sustained by the observation of a second series of cases of which this is one.

Case VI.—Bullet of 0.32 caliber entered the head immediately above the right external angular process of the frontal bone, inflicting a cutaneous wound one-eighth of one inch in diameter; the skin was scorched in an area of three inches, powder-grains were embedded in an oval area of two inches in its long diameter, and there was orbital and subconjunctival hemorrhage. The bullet was firmly imbedded in the bone, which was fissured toward the root of the nose.

The bullet was removed and the inner table of bone was found to be shattered and the dura mater wounded. Drainage was employed for three days. No general symptoms occurred at any time.

Case VII.—Bullet of 0.38 caliber entered the head one-half inch above and in front of the right external auditory meatus; the top of the ear was shot away; powder-grains in area of three inches; skin unburned; tips of hair singed; hemorrhage from right ear; temperature, 99.6° F., pulse 64, respiration, 16; consciousness retained. On the following day the pupils were dilated but responsive to light and accommodation, the cervical muscles were rigid and somewhat painful, and the temperature ranged from 99° to 100.2° F. The patient was then transferred to another hospital, opportunity for explorative examination not having been afforded, and nothing is known of his subsequent history, except that he was discharged from there two months later.

Case VIII.—Bullet of 0.22 caliber entered the head one and one-half inches behind the left external angular process of the frontal bone; wound minute; no burning of hair or skin; smoke area of two inches in diameter; powder-grains embedded in temporal muscle but not in the skin; stellate depressed fracture; bullet embedded in a fragment of bone and lying upon the dura mater, which was black with powder-grains and contused but not lacerated; depressed bone and dura mater powder-stained in area of one inch.

The bullet was removed and the depressed bone elevated by use of trephine and rongeur. No general symptoms followed.

The patient admitted that though not left-handed he had shot himself with his left hand to induce the belief that his wound was homicidal. This case has therefore a medico-legal significance. The fact that a right-handed person was shot in the left temple might seem to justify an inference that the wound was not self-inflicted; but this instance of attempted wilful deception on the part of the wounded person demonstrates the worthlessness of any deduction from such a purely hypothetical premise.

Case IX.—Bullet of 0.38 caliber, Smith & Wesson, entered the head one-fourth inch behind the right ear, making a vertical wound one and one-fourth inches long; another wound extended through the ear into the meatus auditorius externus. There was no burn, smoking or powder-stain of the skin and no embedded grains of powder. The edge of the wound was blackened and the subcutaneous tissues were infiltrated with powder. The osseous wound was two-fifths of one inch in diameter. The probe, on being passed into the petrous structure, detected neither bullet nor loose pieces of bone.

On admission the patient's mental condition was normal; ten minutes afterward three general convulsions occurred in rapid succession and were followed by coma. On the following day the mouth was drawn to the left; an inability to close the right eye was ascertained later to have existed prior to the present injury. The temperature after admission remained at 101° F.

The osseous wound was enlarged with a chisel and the bullet extracted. The bullet was split in its long axis and its two portions extended upon each other at a very obtuse angle, forming a mass one and one-eighth inches long lying in the long axis of the petrous portion, which it seemed to fill. A number of osseous fragments, constituting a considerable portion of the petrous process were removed, the removal of the last portion being followed by a small extrusion of brain matter. The patient recovered without the occurrence of general symptoms.

These cases in their aggregate are fairly rep-

resentative of that minority of pistol-shot wounds of the head which are not immediately fatal. If the one be excluded which failed to reach the hospital ward the fatalities and recoveries are in equal number. One only of the recovering cases was of importance. In this the brain was lacerated and life was probably saved only by operation. In two other instances, Cases VI. and VIII., in which the dura mater was wounded or contused, early operation, if the result of recorded cases in which it was neglected may be taken as a criterion, also saved the patient from mishap. In two of the fatal cases the bullet made complete exit; in the third it was removed from the eyelid, and in the fourth it remained in the brain until death on the thirty-first day. In the final case the bullet was lodged at a site admitting trephination. The preliminary examination, however, revealed a deflection in its course which prevented even a conjecture as to its location, and the hospital had no apparatus for making examinations under the X-rays. Necropsy proved that its retention had no influence in the development of fatal symptoms; it was the fragments of bone and lead which were as usual the source of danger and disaster.

There can be at the present time no reasonable doubt that all pistol-shot wounds of the cranium and all those involving the cranial cavity should be carefully explored and that as far as practicable not only the bullet but all fragments of bone should be removed.

CLINICAL MEMORANDUM.

A CASE OF POLYDACTYLISM.

BY A. L. BENEDICT, M.D.,
OF BUFFALO, N. Y.

THE photographs from which the accompanying cuts were reproduced were taken during one of my vacations, and as the case is entirely outside of my practise they have not been hitherto published. The patient was a boy of seventeen, otherwise normal, and with no significant family history, unless his belonging to the Jewish race, which is the purest and most highly inbred encountered among American Caucasians, has some remote etiologic bearing on the deformity. Each extra digit has a distinct articulation with the fifth metatarsal or metacarpal bone, respectively. The tendons, so far as could be determined, are the same as for the fifth digits. Independent muscular action of the sixth digit is impossible. Two or three years previously, the patient had purposely twisted the sixth toe on to the dorsum of the foot, for greater convenience in wearing shoes. Except for the difficulty of wearing a glove, the patient experiences no difficulty with the hand, and he can catch a ball, pull an oar, and indulge in similar exercises as well as most boys.

MEDICAL PROGRESS.

Sarcoma in the Stomach of a Child Three and a Half Years.—FINLAYSON (*Brit. Med. Jour.*, December 2, 1899) mentions a case of sarcoma of the stomach in a young child which puzzled the physicians during life and which was only recognized at autopsy. Vomiting was a prominent symptom although it did not seem to have any special relation to feeding, and the vomited material was in no wise characteristic. There was constipation alternating with diarrhea. The child was profoundly anemic and his anemia and weakness were progressive up to the time of death. A tumor, which was supposed to be the spleen, was

felt in the left hypochondrium. Pain was not present. At autopsy the tumor was found to occupy the posterior wall and a part of the greater curvature. It measured an inch across the mucous surface and two inches externally. The sarcoma of the spindle-celled variety.

Unusual Gunshot Wound of Brain.—Barker (*Lancet*, December 2, 1899) reports a case in which a man with suicidal intent discharged two shots from a revolver through his mouth upward and backward. For forty-eight days there was occasional vomiting. There was at first no paralysis, but later the power in the left arm and leg was considerably reduced. The temperature was at no time over 100° F. Consciousness was not at any time suspended. After six weeks the vomiting ceased, the slight headache of which he had complained disappeared, and the power of the left arm and leg increased so that he was soon able to walk. Both bullets were shown by skiagraphs to lie within the skull. Making due allowance for the different size of the shadows and that of the man's head, the operator's calculations led him to the conclusion that one of the bullets struck against the vertex and fell backward into the median fissure. In describing the effect of the shot, the patient said that he felt the bullet rattle against the vertex. As long as the presence of the bullet caused no serious symptoms Barker concluded that it was best to leave it alone, but on the sixty-sixth day the patient had a convulsive seizure lasting from three to five minutes. Two days later he had a similar attack and an hour after the second a third; on the following day he had a fourth. On the following day an osteoplastic flap was sawed out and turned back with the base toward the middle line, thus exposing the longitudinal sinus without injuring it. A probe passed along the fissure in the direction in which the bullet was supposed to lie touched the bullet, and it was removed with forceps under the guidance of the little finger. The finger acted better than the probe as during a coughing spell, the latter produced slight injuries to several vessels and to the brain substance. There was, however, very little bleeding. The dura was stitched in place as far as possible and the osteoplastic flap replaced. Consciousness returned rapidly but sensation and motion were absent from the whole left side with the exception of the face. They returned slowly, and a month after operation, while there was fairly good sensation, the use of the left arm and leg was still very imperfect. Afterward the power of the muscles greatly improved, but the epileptic fits recurred so that a year after the injury, Chipault of Paris trephined and separated some adhesions between the two hemispheres. For nine days prior to this operation there were from sixty to one hundred epileptic seizures in a day with complete hemiplegia. After the operation the epileptic attacks disappeared and there was a steady gain in power in the left leg and arm.

Chemical Nature of Enzymes.—From a physiological as well as from a purely chemical standpoint the enzymes, or ferments, form one of the most interesting groups of organic compounds. In *Science*, December 29, 1899, O. Loew classifies them as follows:

1. Enzymes which are intimately connected with nutrition, as diastase, pepsin, trypsin, lipase, etc.

2. Enzymes which cause oxidations—the oxidases.

3. Enzymes which bring on coagulations, the clotting enzymes: rennet, thrombase, pectase.

The first group has been known the longest and best. The practical importance of the others is increasing daily. In addition to these enzymes which act on glucosides, fats, carbohydrates, and true proteins, there are a number of others which are active in limited spheres. Certain fungi and mites attack the keratin in the hair and skin. Certain other insects and fungi attack the chitin of insects' wings. A large and important group is made up of the bacteriolytic ferments, produced by certain kinds of bacteria themselves. These enzymes play an important rôle in the recovery from and immunization against infectious diseases. It is of interest to note that certain bacteria produce enzymes that later kill the bacteria. Thus *bacillus pyocyaneus* "commits suicide by means of its own enzyme." Loew suggests three important questions with reference to these bodies. (1) Are the enzymes proteins or not? (2) How can one explain the fact that a very small amount of an enzyme can transform a relatively large amount of another compound? (3) What is the cause of their quite specific action, the reason that they can only attack a specific compound and not other, even closely related ones? In answer to the first question, it seems probable that different enzymes may exist in every one of the protein groups, and some may exist that are not proteins, although derived therefrom. No satisfactory answer has yet been found for the second question. The closest analogies seem to exist between the catalyptic phenomena known of certain metals. These are dependent, in the case of enzymes, on the liability or activity of chemical interchange whereby enzymes are capable of transforming heat energy into chemical energy. This clinical energy is capable of being transferred to other compounds. The answer to the third question is a much involved chemical one, depending upon molecular structure.

New Method of Skin-grafting.—Kellock (*Lancet*, November 25, 1899) has hit upon a method for providing a large piece of skin for use as a graft. By the ordinary methods, if a thick piece of skin is taken it fails to unite, whereas a thin Thiersch graft, while uniting easily, does not prevent cicatricial contraction. The author's method is to mark out a square piece of skin and to cut on its four sides a thin Thiersch graft, leaving it attached in the central portion which is then dissected up from the subcutaneous tissue. Such a graft, if properly applied to a raw surface will unite almost as readily

as an ordinary Thiersch graft, while its thick center, comprising the whole thickness of the cuticle, limits cicatricial contraction. The wound caused by its removal may be approximated by sutures or may be covered by a thin graft.

Tuberculosis of the Kidney.—Usually cases of tuberculosis of the kidney do not come under the physician's eye until the symptoms are so well marked that a diagnosis is comparatively easy—to make a diagnosis early requires considerable skill. A method described by C. P. Noble and W. W. Babcock (*Amer. Gynecol. and Obstet. Jour.*, December, 1899) enables one to make a diagnosis in an early stage or in a case of obscure character. This method consists in catheterizing the urethra with sterile catheters and collecting the urine. The sediment from the urine thus obtained must then be injected into guinea-pigs. If a kidney is tubercular the urine from it will infect the guinea-pig, as they are extremely susceptible to the tubercle bacilli. The objection to this method of diagnosis is the time required for its completion, as from four to six weeks are necessary. Care must be taken that the catheters and the tubes into which the urine is collected are sterile and that all sources of contamination are avoided. The writers report a case in which the diagnosis, made in this manner, was corroborated by an operation on the affected kidney. The sediment of the urine was used and about 1.5 c.c. from each kidney was injected respectively into two guinea-pigs. When the guinea-pigs were killed the one which received the sediment from the right kidney showed tubercular deposits. The operation on the right kidney showed a large suppurating tubercular kidney.

Action of Euphthalmin.—The physiological action of euphthalmin, a recent substitute of atropin, has been carefully studied in an article by Gelanto Vinci (*Therap. Monatsh.*, December, 1899). In both cold and warm-blooded animals there is noted a primary irritation of the nervous system in the form of restlessness, excitement, increased reflexes, and respiration, then tonic and clonic spasms, opisthotonos, exophthalmos, and disturbed respiration. Later, a general paralysis supervenes, but before death the excess of carbon dioxid may again cause convulsions. Peripheral nerves, especially the motor, suffer paralysis, but this in animals occurs later than the centric changes. The heart shows the characteristic vagus paralysis of atropin, preceded in small doses by a slowing of the pulse. Despite the increased cardiac activity, blood-pressure falls, since the vasomotor system is directly paralyzed. Of especial interest is the salivation caused by instilling the drug into the conjunctiva; it disappears later and is due to irritation and paralysis of the secretory fibers of the chorda tympani. Mydriasis begins fifteen to twenty-five minutes after the use of 2 to 3 drops of a two to ten-per-cent. solution, reaches its maximum in three-quarters to one hour, and disappears after three to eight hours. It is also seen after the internal use. It is due to a paralysis of the nerves of the sphincter iridis, without any irritation of the sympathetic dilator fibers. Conjunctivitis or general symptoms never follow the use of ordinary solutions and the fact that intraocular pressure does not seem to be increased makes its use in glaucoma possible.

Thyroid Extract in Tuberculosis.—In a lecture delivered before the Tuberculosis Commission in Munich by E. Klebs, and reported in the *Berliner klin. Woch.* (December 11, 1899), the author dilates upon the good results attained in tuberculosis by the use of expressed juice of thyroids. The administration of this drug is not entirely empirical but is founded upon well-directed experimentation. Thus, it is well known that there are many cases of tuberculosis in which the changes in the lungs are very slight, while the chief symptoms and danger are referable to the stomach. Most of these cases suffer from *achylia gastrica*, accompanied by a heretofore little observed thyroid atrophy. Klebs had previously experimented upon animals in which the thyroid gland was extirpated and found the same stomach conditions as obtain in tuberculosis. Such animals could be kept alive on fluid diet for a long while, whereas the ingestion of solid food was followed almost immediately by severe nervous manifestations. Following these experiments, he extirpated one of the thyroids of a healthy dog (previously weighed carefully), locating the position and size of the other gland as exactly as possible. Then he injected tubercular toxin subcutaneously, in not sufficient dose to kill, in the dog's body at a distance from the remaining thyroid gland. After ten to twenty such injections he obtained the results anticipated in the stomach of the animal. The gastric contents were studied by means of fistulæ. As a result of the analyses there were found absolutely no HCl and no pepsin. The thyroid gland was found to have decreased in weight and size to almost one-half of its previous dimensions, and the colloid substance had disappeared entirely. The epithelial cells were unchanged in themselves, but were scattered within the lumen of the gland. As a result of these experiments, Klebs conceived the idea of feeding tuberculous patients having severe achylia gastrica with freshly prepared thyroid secretion. To demonstrate his success, he cites two cases in which the bodily weight increased markedly as a result of thyroid feeding.

Treatment of Scabies.—The use of a soap containing as active ingredient the extract of tobacco in scabies and other itchy skin diseases is highly recommended by J. Marcuse (*Therap. Monatsh.*, Dec., 1899). His directions are to wash in warm water morning and evening, and after each cleansing to thoroughly shampoo the entire body with this soap, the foam of which is allowed to dry on the skin. After three or four days of this

treatment, a warm bath is taken, when the cure is generally affected. As advantages of this procedure are mentioned the absence of skin irritation and relapses and the cheapness of the material employed.

Pathology of Aneurism of the Aorta.—Arnold Heller of Kiel (*Münch. Med. Woch.*, Dec. 12, 1899) comes to the conclusion that aortic aneurisms in the majority of cases represent the results of a syphilitic process. After drawing attention to such facts as the great frequency of these aneurisms in syphilitics, the occasional presence of them in both man and wife, and the good results achieved with antiluetic treatment, the author presents sufficient pathologic evidence to warrant his belief that these lesions are but rarely caused by a primary chronic endarteritis. Microscopically the changes manifest themselves in a circumscribed or more diffuse infiltration of round and giant cells, involving primarily the media, along whose vasa vasorum the process is most active. As a result, the muscular element will undergo more or less destruction with obliteration of its nutrient vessels. The new growth will secondarily involve the intima, leading to thickening and even projection into the lumen of the vessel. Atheromatous abscesses which so frequently are seen in chronic endarteritis do not, however, occur. Eventually even the adventitia may be invaded, and the cellular tissue will become more fibrous, so that finally the tunica are hard and cicatricial. The process is analogous to syphilitic lesions in the viscera and differs greatly from chronic endarteritis; in old people, however, the two are often seen combined. While the author thus satisfies himself as to the purely luëtic character of aortic aneurisms, he is not willing to admit that these structures may not occasionally have a different etiological basis. Thus aneurisms by rupture or embolism may occur, and there is no reason to believe that other infectious diseases, such as typhoid, may not lead to changes in the arterial walls with subsequent yielding. In true aneurisms, however, syphilis is the only factor of importance, hence an active antisyphilitic treatment should always be advised.

Heroin and Its Advantages.—The usefulness of heroin, a derivative of morphin, in allaying the cough of phthisis, acute and chronic bronchitis, and pneumonia, is strongly urged by H. D. Fulton (*N. Y. Med. Jour.*, Dec. 30, 1899). In the phthisis cases in which the patient is harassed by an almost incessant cough or by severe paroxysms occurring especially at night, the value of this drug is particularly noticeable. It is usually administered in $^1/_{16}$ grain doses every three hours, and is followed by a marked freedom from cough and thereby restful nights. It does not seem to require an increase in dosage, and stomach symptoms appear only when large doses are prescribed. In acute bronchitis it seems to ameliorate somewhat the severity of the attacks, but its chief indication is to tranquilize the persistent cough. A solution of heroin for hypodermatic administration may be prepared by the addition of a small amount of acetic acid and will be found equally efficacious as morphin and less objectionable in cases of spasmodic asthma.

Injection Treatment of Pleurisy.—An interesting report of the results following the treatment of serous effusions into the pleural cavity by the injection of irritants is given by C. H. Lewis (*Med. Record*, Dec. 30, 1899). The methods of emptying a pleural cavity of fluid are (1) by aspiration and (2) by absorption through the lymphatic channels. The former, which is by far the more rapid, would be an ideal method were it not for the frequent recurrence of the fluid and the necessity for repeated operations. When spontaneous absorption occurs it usually leads to permanent results, but it is generally so slow, even when aided by the drainage of the system through the bowels, kidneys and skin, that the patient becomes greatly debilitated. When nature produces a permanent cure the surfaces of the pleura are found to be firmly glued together, preventing any encroachment of fluid. The object of the injection treatment is therefore to imitate nature by stimulating the exudation of fibrin, which acts as a cement substance as the fluid is absorbed. In order to safely inject an irritating solution so that it will act upon all surfaces bathed by the serous effusion, certain conditions must be fulfilled. The irritant must be in permanent solution, it must be aseptic, and the volume of the fluid must not be changed. Experiments were made with iodin, permanganate of potash, and the analine dyes, fuchsin and methylene blue. All proved unsatisfactory except the blue, which is antiseptic; anodyn has diuretic properties and is easily detected in the urine. The ideal vehicle for this irritant was found to be the serum freshly drawn from the pleural cavity, which is a good solvent and at least would introduce no new germs. A large aspirating syringe was used with a rubber tube attached to the outflow tube of the syringe and extending into a glass graduate which holds the methylene blue. A glass rod for mixing the blue and serum was inserted with the rubber tube into the graduate and the entrance plugged with cotton. The whole outfit could then be easily sterilized. Twenty cases of pleurisy with effusion were treated by this method. From eight to fifteen grains of methylene blue were mixed with from fifty to one hundred cubic centimeters of the fluid, withdrawn and then reinjected. All the patients were discharged cured on an average of 13.1 days after the injection was made. In four cases paracentesis was performed a few days after injection without apparently hastening the convalescence, and internal medication did not materially affect the recovery. It seems reasonable to suppose that the antiseptic power of the blue acts directly upon the germ which in many cases is undoubtedly the tubercle bacillus and also stimulates the exudation of the fibrin cement.

Surgical Treatment of Phthisis.—W. C. WOOD (*N. Y. Med. Jour.*, Dec. 30, 1899) mentions four methods of surgical treatment in phthisis: Aspiration and medication; pneumonotomy; pneumonectomy; and obliteration of the cavity by causing collapse of the lung. Aspiration is easy and safe, but unsatisfactory because good drainage is impossible and direct medication futile. Pneumonectomy is satisfactory because of good drainage. It is indicated when the tuberculous involvement is not extensive but the patient is suffering from septic symptoms of an easily recognized cavity, in the hope that relief from sepsis will allow the tuberculous lesion to heal. The operation consists of superiosteal resection of a rib and incision of the parietal pleura. If the visceral pleura is not adherent to the parietes, one may do either a primary incision of the lung or wait until adhesions have formed. An aspirating needle is used to determine the location of the cavity; and the lung is incised with the cautery if it is soft and inflamed, or with the knife if it is hard. Irrigation is not admissible and the cavity contents must be kept from the bronchi. The lung is not sensitive. Pneumonectomy is not a legitimate procedure for pulmonary tuberculosis. Obliteration of the cavity by causing collapse of the lung results from injecting nitrogen into the pleural cavity. The enforced rest of the lung assists cicitrization. The gas should be left in the pleura for from three to six months; it remains unchanged and when it is withdrawn the lung readily expands. Septic infection and injection of nitrogen into the lungs must be avoided. Patients consent readily to this procedure and receive immediate benefit. A sufficient number of cases have not yet been reported to establish its general application.

The Thyroid and the Menopause.—It is well-known that there is some connection between the generative organs of both sexes and the thyroid gland. C. R. BURR (*Boston Med. and Surg. Jour.*, December 21, 1899) reports the case of a woman, fifty-six years of age, who had an apoplectic stroke, nearly a year and a half after her menses had ceased, in which she lost power of speech and the use of her right side. Since the menopause she has had the numerous nervous symptoms generally attributed to that period. There were flushings, neuralgias, hysterical attacks, a rapid pulse, and loss of weight. Nine months after the apoplectic attack there was marked tremulousness, flushed face, and an injected eye. Speech was thick. She perspired profusely, was markedly emotional, and her pulse was from 100 to 120. She could not endure any pressure about the neck. Both eyes were prominent and the thyroid gland was enlarged. Tincture of belladonna, ℥ ii t. i. d., was prescribed, as the writer decided that it was a case of exophthalmic goiter. At the end of two weeks the sense of oppression around the neck had disappeared, the thyroid could hardly be felt, all the nervous symptoms were diminished or absent, and the eyes were no longer prominent.

The thyroid is congested during menstruation, coition, pregnancy, and accouchement. It is not known definitely whether its secretion is also increased, as it is with the congestion in exophthalmic goiter. It would appear from the above case, the writer thinks, that the menopause caused the congestion of the gland, and that the active principle of the secretion caused an auto-intoxication, as in exophthalmic goiter. The symptoms of the menopause are very similar to the secondary symptoms of thyroidal intoxication. A number of other symptoms presented by the patient were also attributed to the intoxication caused by the excess of thyreoglobulin in the circulation.

Calculus in the Ureter.—H. MORRIS (*Lancet*, December 16, 1899) has tabulated a number of cases in which operation was performed for ureteral calculus. It is necessary to note the seat of impaction. In 19 it was within two inches of the kidney, in 15 just before passing through the vesical wall, and in 11 about at the level of the brim of the pelvis. It is worth remembering that 12 of the 15 cases in which impaction at the lower end occurred were in women. In most of the cases in which the stone was impacted near the renal end it was discovered after exploration of the kidney, the kidney itself containing no stone. Whether or not a calculus has been found in the kidney, a surgeon should never conclude a nephrotomy for stone without passing a probe into the ureter. In the present state of our knowledge of the symptoms of stone in the kidney and stone in the ureter, the two conditions cannot always be differentiated; since with stone in the kidney the greatest pain and tenderness may be in the course of the ureter, while in case of impacted ureteral calculus there may be other stones in the kidney, giving rise to pain and tenderness in that organ. In very thin persons a stone impacted above the brim of the pelvis has sometimes been felt. If the stone is near the bladder ecchymosis around the ureteral orifice may be detected by the cystoscope. Attacks of pain and hematuria, extending over some days or weeks, and gradually progressing downward, should arouse suspicion of ureteral calculus. A small calculus with sharp processes is apt to stick in the wall of the ureter, and give more trouble than a larger and smoother one. If both ureters are obstructed at the same time fatal uremia is likely to occur. Some have asserted that if a calculus exists in only one ureter reflex action may stop the flow of urine through the other kidney. Morris denies that such a mishap can take place if the other kidney is structurally healthy. Dilatation of the kidney is apt to occur in those cases in which the calculus is in the upper end of the ureter and from time to time slips back into the pelvis of the kidney. If it remains in the ureter the latter will be permanently blocked either by the calculus itself or by the fibrous tissue which forms around it. Under such circumstances the kidney will in time be

converted into a fibrous mass or a small sac. If a calculus is known to have blocked a ureter, medicinal treatment should not be long continued on account of danger to the kidney and even to the life of the patient. Extraperitoneal ureterotomy should be performed and the calculus removed. If possible the calculus should be displaced upward and removed a little above the point from which it has been lodged; by this means an incision through the damaged wall is avoided, and if the calculus is below the pelvic brim the operation is greatly simplified by lifting the calculus out of the hollow of the sacrum. In the cases reported by Morris, 33 patients recovered after operation and 12 died. It is only fair to state, however, that in most of the fatal cases obstruction or even complete suppression of urine had lasted for several days before operation.

Antitussin in Whooping-Cough.—There are few drugs in the Pharmacopeia which have not been used in the treatment of this affection and with all of them the result has been doubtful. Bromoform, antipyrin, pertussin (Taeschner's) have all been weighed in the balance and found wanting. In the *Berliner klin. Woch.* (December 11, 1899) MAX HEIM gives the results of his experience in 16 cases of whooping-cough treated with the very latest preparation, namely, antitussin. This is an organic compound of fluorin mixed with vaselin and wool-fat (di-fluor-di-phenyl, 5; vaselin, 10; adep. lanæ hydros, 85 parts). In many of the cases failure had followed the use of the above-mentioned favorites, even pertussin, about which so many favorable reports have been heard. In no instance did antitussin fail the author in the attainment of much-hoped for results. As the fluorids are all badly borne by the stomach the administration of antitussin is best carried out in the stated form of an ointment which is applied to the neck, chest, and interscapular region of the back. Before applying it, however, these regions must be carefully washed with soft soap and rubbed dry with a rough towel. The quantity of ointment to be used should be about two or three drams and the rubbing should be continued until all the salve has disappeared. In 7 cases the treatment was begun before the convulsive stage was reached, the other 9 cases after convulsive coughing seizures had made their appearance. The diagnosis in the first series of cases was naturally difficult but the author was enabled to arrive at it partly by means of the circumscribed redness and swelling in the region of the vocal bands (Hagedorn), and partly by the fact that the disease was rampant in the neighborhood at the time and its transmission from patient to patient easily demonstrable. The second series of patients was largely made up of severe and even dangerous ones. The patients were some of the age of only four months, and their environment of the worst possible; the attacks were of severe nature, followed frequently by epistaxis; the general health of the patients was very poor, and in many cases only a fatal issue seemed possible. In every single case, however, after the application of antitussin, there appeared a speedy and at times surprisingly complete relief from attacks. None of the ordinary sequelæ of whooping-cough such as bronchiectases, cheesy degeneration, and so on, was demonstrated by the author. He follows the presentation of his cases with several general considerations, *viz.*: (1) Antitussin makes the attacks of pertussis much milder, changing the character of the disease to a purely catarrhal one; (2) the drug loosens the phlegm and mucus markedly, allowing the patient to relieve himself with ease; (3) the number of attacks diminishes as early as the second day of treatment to one-half, and daily thereafter until entirely gone. The period of convulsions, variously estimated at from five to ten weeks, is reduced to from a few days to at most two weeks; (4) as antitussin is comparatively non-poisonous in the amount used, no untoward results of its administration are witnessed. In all throat and laryngeal affections the preparations of fluorin, especially antitussin, are highly recommended. They relieve the catarrhal conditions and the many annoying reflexes (sneezing, coughing, etc.), as well, in a remarkably short time. Antitussin, therefore, is a drug which seems to be the one much sought for by the medical profession for many a year.

Practical Points on Diseases of the Rectum.—All physicians recognize the difficulty of obtaining a patient's consent to a rectal examination when the symptoms point to some local disturbance. Perhaps more success would be met with if the physician thoroughly appreciated the natural hesitancy toward such an examination which nearly all patients most properly feel. Many valuable hints in regard to the necessity of giving careful attention to the history of the case and of reassuring the patient before an examination is suggested, together with a few most practical points upon the more common diseases of the rectum, are given by L. H. ADLER, JR. (*N. Y. Med. Jour.*, Dec. 30, 1899). He most strenuously insists upon the desirability of a local examination before a diagnosis is ventured and most certainly before treatment is begun. To illustrate his remarks he quotes from Dr. Charles B. Kelsey, who says, "In my own practise I am guided by the simple rule that patients, male or female, who have not yet come to the point which makes them willing to submit to an examination, have not yet reached a point which admits of treatment."

With reference to proctitis and periproctitis considerable stress is laid upon the tendency toward suppuration, which is so often followed by fistula and requires free incisions of the affected parts. In cases of fistula the internal opening is to be found in most cases between the two sphincter muscles and not, where most practitioners seek it, higher in the rectum. The injection

of a colored solution, such as milk or potassium permanganate, may assist in the location of the internal opening. Simple cases of fistula may be operated on with very little pain by the use of cocain or eucain and the patient need not be confined to bed. Fissure of the anus gives such characteristic symptoms of severe pain during and especially immediately after defecation that a diagnosis can usually be made, but an examination should always be made. The best medical treatment consists in the use of iodoform, preferably in the form of a 10-grain suppository, of which one should be carefully inserted into the rectum half an hour before an expected movement and another immediately after the passage has occurred. Hemorrhoids do not always require operative treatment. In the formative stage frequent ablutions of the part with cold water will allay, if not abort, inflammatory tendencies of the veins which otherwise lead to piles. Acute inflammation is not a contra-indication to operation when the case demands such a measure. Furthermore the consent of a patient can be more readily obtained while suffering, and external hemorrhoids may be painlessly removed with an alleviation of all the symptoms. The correct way of ascertaining the presence of a benign growth, such as a polypus, is to carry the finger well up the bowel away from the side to be explored, and then, by steady pressure, to sweep the finger downward, continuing this procedure all around the bowel. In this way a polypus, if present, will be caught between the finger and the wall of the rectum.

Treatment of Tubercular Glands.—W. W. Cheyne (*Lancet*, Dec. 16, 1899) has come to the conclusion that tuberculosis of the cervical glands may be due to direct infection with bacilli entering them through the throat or some other organ. In many cases, however, trouble with the teeth, tonsils, etc., leads to an acute infection of the glands which, when it subsides, leaves them in a weakened condition. In consequence they form favorable soil for the growth of tubercle bacilli brought to them by the blood. In a similar manner tuberculosis develops in a joint which has been weakened by a sprain. Tuberculous cervical glands may be considered under five heads. There may be a number of small hard glands which show no tendency to become softened or to mat together. Patients in this condition should be kept in good hygienic surroundings and treated medicinally. The glands may grow to such an extent that they cause a great deformity. This condition is usually bilateral. It may last for a long time without the occurrence of suppuration or the matting together of the glands. Such glands when removed generally contain caseous patches or calcareous nodules. Hygienic treatment has little effect upon glands in this condition, and a free incision should be made and all the affected glands removed as early as possible. The third type of cervical tubercular adenitis is one in which one or more glands grow rapidly, suppurate, and become matted together. If left to themselves their pus breaks through the skin. The neck of a patient in this condition presents numerous abscesses and ulcers. Incision of a suppurating gland, followed by a scraping away of its contents, is an unsatisfactory procedure, since other glands remain and rapidly enlarge and suppurate. As in the former class of cases a wide incision should be made and all the enlarged glands removed. The teeth, tonsils, etc., of the patient should be examined and treated if necessary. In a fourth class of cases suppuration remains limited to one or possibly two glands; it goes on until the gland substance has been entirely destroyed. The condition is then that of an abscess, usually limited to the gland capsule, and therefore beneath the deep fascia. If this is the case it should be entirely excised. Before it breaks through the fascia, its own substance has usually been completely destroyed. Hence the abscess may be opened and its cavity cleaned out, scraped and injected with iodoform and glycerin emulsion. A fifth condition in which such patients present themselves is one in which there are one or more sinuses leading down to remnants of gland structure. Such sinuses are themselves of a tubercular character and if possible they should be thoroughly excised. If this is not feasible each sinus should be scraped and swabbed with pure carbolic acid.

The situation in which the glands are most commonly affected is the anterior triangle of the neck. If recurrence is to be avoided it is necessary not only to remove all fat and glandular substance, leaving the vessels and muscles clean, but also to pull aside the sternomastoid in order to remove the fat and glands beneath it. The operation is simplified if in its very beginning the internal jugular vein is exposed at the lower part, it can then be avoided while the affected tissue is dissected away from it. If the glands have suppurated and are closely attached to the vein, the operator need not hesitate to divide it between ligatures and remove it. In working beneath the sternomastoid muscle care should be taken not to injure the spinal accessory nerve. The best plan is to turn back the muscle and expose the nerve in its upper portion, or else to divide the muscle. The glands may then be dissected away from its under surface, both above and below the nerve. If the operator proceeds in this methodical way recurrences in the anterior triangle will rarely take place.

Uterine Scrapings and Diagnosis of Cancer.—Pain, discharge, and hemorrhage were considered formerly to be the characteristic symptoms of cancer of the uterus. To try to make an early diagnosis from these symptoms J. Wiener (*Am. Jour. of Obstet.*, Dec., 1899) thinks would be impossible and dangerous. He says there are no symptoms that are pathognomonic of cancer of the uterus. Of these three symptoms, pain is of least value, as it does not occur until late in the disease. When discharge is present in the early

stages it is not due to the new growth, but to a pre-existing endometritis. Hemorrhage is a more valuable aid in that it arouses our suspicions—it cannot do more, but it should do that, especially at the time of the menopause. Many times the menopause is held responsible for symptoms which are in reality due to a beginning malignant growth. Wiener thinks that we are too apt to look for the disease in older women and to overlook it in younger. He cites statistics which show that the disease occurs between the ages of twenty-one and forty-five in 62.4 per cent. of 705 cases. Endometritis is a very important factor in the etiology. The methods which will help us to reach a diagnosis are inspection and palpation, dilatation of the uterine canal and introduction of the finger, and microscopical examination of uterine scrapings. Inspection and palpation do not tell of the character of a growth even if we succeed in seeing or feeling one. Introduction of the finger into the dilated uterine canal will only allow one to feel an ulceration or a new growth, and simply suggests the part to scrape most thoroughly. Microscopical examination of uterine scrapings is the only reliable way of making an early diagnosis of uterine cancer. A differential diagnosis must not be made from the scrapings between uterine cancer and endometritis, glandular or interstitial, necrotic myomata, polypi, placenta retenta, and abortion. Wiener refers to statistics in which out of 58 cases of hysterectomy for uterine cancer, 41 were diagnosed solely from the microscopical examination of the uterine scrapings, and the diagnosis confirmed. He also presents four cases of his own in which an early diagnosis was made from scrapings of the uterus. Therefore, from his own experience and from cases cited, he concludes that cancer of the uterus should be diagnosed with the microscope, that it should be suspected at all ages—in virgins, in nulliparæ, as well as in multiparæ—and that a typical hemorrhage should always arouse suspicion, even at the time of the menopause. With early diagnosis and early operations, the mortality due to malignant disease of the uterus would be much lowered. Sixteen illustrations accompany the article.

A New Infusion Mixture.—It is well known that the addition of calcium and other salts to isotonic solutions favorably influences the heart's action, but it is less readily recognized that an ideal infusion mixture should contain among its constituents a substance capable of binding the carbon dioxid which has accumulated in the remaining blood. Normally this is accomplished by the presence of an alkaline globulin compound in the circulatory blood, which, in the presence of carbon dioxid, splits up with the formation of an alkaline carbonate and free globulin. It is not likely that these unstable compounds will maintain their integrity during the process of transfusion of blood from one individual to another; quite to the contrary, it is probable that the heart is still further weakened by this procedure due to the potassium salts which are liberated by the breaking down of blood-corpuscles which always occurs here. A. SCHIEKING (*Thera. Monatsh.*, Dec., 1899) states that it may be impossible to artificially reproduce the complex globulin compounds, but he has found in sodium saccharate a valuable drug which seems to possess all the properties of the former. This salt is a gelatinous, freely soluble, bitter chemical, which in the presence of carbon dioxid forms sodium carbonate and sugar, thus binding the gas. The clinical use of this body has fully borne out the expectations which such experiments as the reanimation of apparently dead hearts of frogs and also of warm-blooded animals permitted the author to hope for. No deleterious effects were ever noticed, and good results have been seen even where the use of the usual salt solution failed to improve the patient. A solution containing 0.03 per cent. of the compound with 0.7 per cent. sodium chlorid is recommended, but care must be taken that the mixture contains neither free sodium hydrate nor sugar. The internal use of the saccharate is also advised in all cases where alkalies were formerly employed.

Treatment of the Initial Lesion of Syphilis.—When excision or destruction by other means is not feasible, the following methods may be employed according to the location of the lesion:

1. Within the vagina or at the portio vaginalis. Apply mercurial ointment on cylindrical or round cotton pads to which a thread is attached to facilitate removal. In pregnant woman no pad, however small, should be introduced, but rather a suppository made as follows:

℞ Ung. hydrarg. . . . . gr. lxxv
Ol. theobrom. . . . . ʒ ii ss.
M. Ft. suppos. No. X. Sig. Insert in vagina.

Or the lesion may be painted with one of the following solutions:

A.
℞ Hydrarg. chlor. corros. . . . . gr. ¾—iii
Spiritus. . . . . } aa. . . . . ʒ ii ss.
Aetheris sulph. }
M. Sig. External use.

B.
℞ Hydr. chlor. corros. . . . . gr.. ½—iii
Collodii. . . . . }
Aetheris sulph. } . . . . . ʒ ii ss
Ol. olivæ. . . . . ♏. iii.
M. Sig. External use.

2. On the buccal mucous membrane, tonsils, etc. Paint with the alcoholic-etheral solution of corrosive sublimate given above.

3. On the skin, or at the junction of skin and mucous membrane (lips, alæ nasi, female genitals, etc.). Cover the lesion with a piece of gray plaster, making it fit as smoothly as possible by means of incisions in its edge. Let it extend well over the border of the lesion. The renewal of the plaster should depend on the amount of secretion. The induration clears up rapidly, while ulcerations and erosions heal most satisfactorily by this method.—Lang, "XX. Century Practice."

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JANUARY 6, 1900.

THE PAST YEAR'S ADVANCES IN MEDICINE AND SURGERY.

ONE of the striking features of the past year is the position that surgery has taken in the treatment of diseases of the gall-bladder and gall-ducts. These affections have been wont to run a most uncertain and unsatisfactory course under medicinal management, and it has now become clear that early operative intervention is destined to take them out of the physician's hands. Expectant treatment for gall-stones, once it has become manifest that the attacks of pain are recurring, will soon be a thing of the past.

In the treatment of intestinal obstruction and intussusception surgery has also asserted itself, and operation within the first twenty-four hours after diagnosis, or as soon as it is clear that medical measures fail to give relief, is henceforth to be the indication. In cases of typhoid perforation, operative interference as soon as the diagnosis is established has been emphasized, during the past year, as the only justifiable rule of procedure.

Two successful methods of treatment seem worthy of particular mention in the review of the year. Pagenstecher reported a case of stab-wound of the left ventricle of the heart, in which, twenty-four hours after its infliction, he successfully inserted four sutures. The three deep sutures penetrated the entire thickness of the heart muscle, leaving only the endocardium intact. It was with the greatest difficulty that the uppermost suture could be inserted, because its site was not visible except when the heart raised itself up and twisted on its axis during systole. The manipulations necessary for the insertion of the sutures did not perceptibly disturb the heart's rhythm or action. This is the tenth case of active surgical interference in wounds of the heart, and six of them have been successful. The mortality of these cases under expectant treatment was from 80 to 90 per cent. The second notable success was the cure of four cases of volvulus, with all the classical symptoms of that affection, by the simple method of having the patient, while maintaining as nearly as possible a horizontal position, roll over in bed. The attempt to turn, if made in the direction of the twist in the intestine, is followed by immediate increase of pain, while even a partial turn in the opposite direction brings relief, and several turns untwist the ileus completely, with absolute cessation of symptoms.

In medicine the notable event of the year has been the definite determination that a special form of mosquito is the host and the carrier of malarial infection. It is evident that the discoveries in this line are soon to bear abundant fruit in the prophylaxis against the disease and its ultimate eradication from infected regions. In general the advance of civilized nations into the tropics has led to a great increase of knowledge of tropical diseases. England and Germany, as well as our own country, have taken a commendable interest in this work, and it is evident that the question of the habitability of the tropics by white men is soon to be settled in the affirmative.

Progress in general medicine has been more along the line of better appreciation of details than distinguished by any single noteworthy advance. Improvements even in such old-fashioned diagnostic methods as inspection and palpation are not wanting. The shadow that the diaphragm makes on the chest-wall in thin people and the corresponding shadow of the abdomen made by a dilated and partially filled stomach, under similar conditions, have become significant features of physical diagnosis. The percussion of the vertebral spine is now made to convey valuable information for the solution of such difficult diagnostic problems as aneurism, enlargement of the intra-thoracic glands, and mediastinal tumors. The

vertebræ act excellently as pleximeters. The use of certain organs as the spleen and liver as pleximeters in percussion, to elicit information from beneath them, has also developed, and promises to be of value.

In some directions physicians have been undoing the work of too hasty conclusions. The resistive vitality of the individual rather than the virulence of microbes is now recognized as the determining factor in the course of disease. The claims of discoverers of the specific germ of rheumatism have brought out more clearly than ever that in even simple acute rheumatism there is present not a single entity, but a series of pathological conditions due to many causes. The fact that contributions of the great body of the profession rather than that of a single genius have influenced medicine during the past year, is a matter for congratulation. It is well known that gradual progress made all along the line is more effective in permanent advance than sudden bounds which are apt to overleap the mark, leaving the future to discount unwarranted assumptions.

HORSELESS VEHICLES AND MUNICIPAL HEALTH.

In what unexpected directions new inventions may be productive of important results, is frequently a matter of great surprise. Who could have foreseen that the introduction of gas as an illuminating agent would work a revolution in materia medica and therapeutics? Yet this has actually happened. The much-used, also much-abused, analgesics and antipyretics are mainly coal-tar derivatives obtained from a by-product.

Equally surprising will doubtless be the achievement of the horseless vehicle in its effect upon the healthfulness of cities. In an article in the December number of the *Automobile Magazine*, J. J. Walsh points out that there are certain diseases whose incidence in our great cities will greatly diminish as the results of the absence of the horse from city streets. Tetanus will very probably disappear completely. It is on horse fodder that the germ is introduced into cities and the principal sources of its dissemination are the intestinal discharges of the animal. With the elimination of the horse, therefore, will doubtless disappear also that dread disease.

There are certain indirect effects, moreover, which seem worthy of consideration. The disposing of horse droppings constitutes the principal work of the street-cleaning department and their absence will greatly simplify the cleaning of streets. Then with the advent of the horseless vehicles universally comes the rubber tire. This means absence of noise and freedom from its ceaseless wear and tear upon the nervous system.

From a sanitary point of view there is every reason for those who are interested in municipal health to encourage in every possible way the automobile movement. Accidents from the new motive power will undoubtedly occur. The foolish and careless will abuse a good thing despite every precaution. Mechanism will sometimes get out of order. It is not at all probable, however, that the accidents under a horseless régime will be comparable in frequency to the numerous casualties that happen now. There are therefore many reasons to rejoice that we shall soon inaugurate in our large cities the horseless era.

THE AMERICAN CIGARETTE.

Among the many lines of scientific inquiry that have been undertaken by the London *Lancet*, not the least important is its investigation into the subject of tobacco and its adulteration. Through its Analytical Sanitary Commission it has had this subject under consideration at successive intervals since the year 1853. Its report of that year was based on the analysis of a great number of samples of tobacco and cigars purchased from shops in London. The decision then reached was that there was no evidence to show that such adulteration as was discovered was of a kind to produce injury to health.

Since that date the cigarette has been introduced in every-day life, and in 1888 this same commission analyzed the chemical constituents found in the tobacco and the paper of cigarettes and reported that there was no trace of opium nor any unclassified alkaloid in the tobacco, not a trace of chlorid or arsenic in the paper, but that there was a faint trace of copper due to the metallic lettering on the paper wrapper. The exaggerated statements concerning the adulteration of cigarettes and the poisonous constituents of the paper continue unabated, and a more recent investigation of cigarettes purchased in New York and the same brands of cigarettes sold in London has been made by the same commission. The results of this last investigation are published in the issue of the *Lancet* of December 9th as follows: "As a matter of fact, the results in both cases show no foundation whatever for the exaggerated statements that have been made. Foreign toxic substances

were not found in a single instance; amongst those looked for both in the paper wrapper and in the tobacco were morphia, phosphorus, arsenic, mercury, copper, and other heavy metals. The only evidence of a metal being present was in the case of copper in the paper. The quantity present was so excessively minute as to put any question of its being injurious beyond consideration. To sum up, there is not a single feature in these numerous results upon which can be fairly based any allegation of the presence of a substance producing injury to health."

It seems from this that the injurious effects of cigarette smoking result from the excessive or premature use of them. The almost constant custom among cigarette-smokers of drawing the smoke into the lungs may also be mentioned in this connection, although the commission says that it is doubtful whether any nicotine ever reaches the mouth of the smoker except that present in the moistened tobacco which is in contact with the lips. The smoke products of tobacco do not contain any important quantity of nicotine. There are toxic bodies, however, in the smoke. These are related to that interesting series of organic bases known to chemists as pyridines, but about which not much is at present known.

ECHOES AND NEWS.

NEW YORK.

Bellevue Park Completed.—The yard of Bellevue Hospital has been changed into a park, which was opened on December 23d by the playing of a spouting fountain of quite splendid proportions.

New St. John's Hospital.—The new St. John's Hospital, at Twelfth street and Jackson avenue, Long Island City, will be consecrated and will have its doors thrown open on January 7th. This hospital, which is under the direction of the Sisters of St. Joseph, will accommodate over 200 patients.

Dr. Weir a Delegate to the International Congress.—Dr. Robert F. Weir, President of the American Surgical Association, has been appointed by the Secretary of State one of the delegates of the United States Government to the Thirteenth International Congress of Medicine to to be held at Paris, August 2 to 9, 1900.

Doctor a Morphin Victim.—Dr. Edward M. Bangs, forty years of age, a guest of the Cosmopolitan Hotel, was committed to Bellevue Hospital on December 29th to have his sanity determined. He was found on reception to be a victim of the morphin habit. Dr. Bangs is not a resident of this city. His home is not known.

Busy Day for Ambulance Surgeons.—New Year's day was a very busy one in the ambulance department at Bellevue Hospital. Fifty-six calls were answered. This is the heaviest day's work since the summer of 1896, when so many people were prostrated by the heat. At that time 154 calls were answered one day and 101 another day by the Bellevue surgeons.

A Nurse's Funeral.—Miss Margaret Alice Burr, twenty-five years of age, a nurse in the City Hospital on Blackwell's Island, died there on December 23d. Her body was taken to her home in Troy. The hospital internes and Miss Burr's thirty companions, the latter in their uniforms, marched to the Island dock and stood uncovered until the boat conveying the body was in mid-stream.

Priest as an Ambulance.—A negro painter, while at work on a new building on Elton avenue, fell three stories to the ground and sustained several fractures. A crowd gathered but nothing was done to help the injured man until Father Murphy, a Catholic priest, came along. He took the man on his shoulders and carried him seven blocks to a drug-store, whence he called up an ambulance from Fordham Hospital.

Contagious Diseases.—The Health Department submits the following report for the week ending December 30, 1899: Measles, 450 cases and 20 deaths; diphtheria, 257 cases and 46 deaths; laryngeal diphtheria (croup), 10 cases and 7 deaths; scarlet fever, 154 cases and 17 deaths; chicken-pox, 28 cases; tuberculosis, 105 cases and 142 deaths; typhoid fever, 33 cases and 13 deaths; cerebrospinal meningitis, 5 deaths. Totals, 1037 cases and 250 deaths.

The Post-Graduate Hospital.—The fifteenth annual report of the Post-Graduate Hospital states that 1617 free patients were treated as in-patients and were given 38,313 days of care. The whole number of patients was 2688, and 1447 patients were visited in their homes, without charge. There was free home attendance in 368 obstetric cases. An account of the hospital's work on the East Side is given, and an appeal is made for the endowment of the laboratory and the lying-in department.

The Academy of Medicine.—The Treasurer's report of the New York Academy of Medicine for the year ending December 15, 1899, has been published. The report certainly shows a most flourishing condition financially. The report of the trustees shows an indebtedness on the building of $2000.00. Since the Treasurer's account was audited, however, Fellows have subscribed an amount sufficient to meet this outstanding note and the institution, therefore, begins the new year free from debt.

Alcoholism and Traumatism.—A Brooklyn policeman recently found a man in a helpless con-

dition in Atlantic avenue. The surgeon who was summoned made the diagnosis of acute alcoholism. The man was taken to the police station, where he lay until next morning, when the police, not being able to arouse him, again summoned the ambulance. This time the surgeon diagnosed a fractured skull. A number of similar cases have occurred in Brooklyn of late. They occur much too frequently in a great many places.

Brooklyn Hospital Surrenders.—Negotiations are in progress for the transfer of the Brooklyn Homeopathic Hospital, Dispensary, and Training School for Nurses, by the trustees, to the city authorities. It is expected that the control shall rest in the city along with the actual property and obligations of the institution, and that in return the city shall agree to maintain it under the homeopathic system. The property is worth about $150,000, and there are obligations amounting to $60,000. The hospital was organized in 1852.

Death of Dr. Winston.—Dr. Gustavus S. Winston, son of the late Frederick S. Winston, who was for many years President of the Mutual Life Insurance Company, died on December 29th from apoplexy. He was sixty-six years old. He was a graduate of Columbia and of the College of Physicians and Surgeons. In the Civil War he was surgeon of the Eighth Regiment. Having been captured and confined in Libby Prison, he escaped through friends of the Winston family, who, although Southerners, sympathized with the North. Dr. Winston was for about twenty-five years one of the medical directors of the Mutual Life Insurance Company, and for the greater part of that time was its chief director. He was a member of a number of clubs, a charter member of several medical societies, and a Fellow of the New York Academy of Medicine. He was Visiting Physician to St. Francis Hospital.

St. Bartholomew's Year Book.—The year book of the Parish of St. Bartholomew was issued on December 29th. The receipts during the year were upward of $208,000 and the expenditures were $207,729.90. The charities of the parish include the clinic, the employment bureau, the loan bureau, the penny provident fund, the kindergarten, the tailor shop, and the fresh-air fund. Through one or another of the many benevolent agencies incorporated within this parish hundreds of persons have been aided during the past year in securing food and work. This book affords an opportunity to contrast church work as it was in the past and as it is in the present day. Formerly, the spiritual welfare of the parishioner and his preparation for a future life were alone considered. Nowadays a large, perhaps the largest, part of the work of a great church in a large city seems to lie in the direction of improving humankind as regards material conditions and during the present life. Two of the most faithful and most earnest workers in the parish, Cornelius Vanderbilt and William H. Appleton, have died during the past year.

State Care of Consumptives.—Since the adjournment of the last Legislature at Albany a special committee of the State Board of Charities, composed of Commissioners Harvey W. Putnam of Buffalo, Enoch V. Stoddard of Rochester, and Dr. Stephen Smith of New York City, has been considering the establishment of State hospitals for consumptives and the promulgation by the State Board of Health of regulations which will tend to prevent the spread of tuberculosis. The committee will submit its report to the State Board of Charities some time during this month. The committee will recommend that every locality able to have a hospital for consumptives should have one, and that the State should erect and maintain one or more hospitals where localities unable to maintain local hospitals might send their patients and pay for their care and maintenance. It will also recommend that local boards of health should have more power in dealing with consumption; that it should be declared to be a contagious disease, and that the boards of health should have power to establish rules and regulations to protect the public from contagion.

CHICAGO.

Examinations for Medical Inspectorships.—The Civil-Service Commission recently completed the returns of the examination for positions as medical inspectors in the Chicago public schools. Of the 250 physicians who took the examination, 93 failed to secure the required standing. Many of these were old, gray-haired, and experienced physicians.

Many Criminals Convicted.—States Attorney Deneen reports that the year 1899 has been an unusually busy one in his office from the standpoint of criminology. There were 6911 cases on the docket and 4278 disposed of, there being 3117 convictions; there were 219 acquittals, and 150 defendants were found not guilty by the court, while 93 cases were nolled, and 45 were nolled by request of the prosecuting witness.

Examination of Osteopaths.—On December 29, 1899, the Illinois State Board of Health conducted a special examination for licenses to practise in Illinois as osteopaths. The class numbered thirty-four, most of whom were students of the American School of Osteopathy at Kirksville, Mo. The branches in which they were required to pass a satisfactory examination were anatomy, physiology, chemistry, histology, pathology, and hygiene.

Consumptive Hospital in Chicago.—The Citizens' Committee, which has taken the initiative for the erection of a $150,000 hospital for consumptives, under the auspices of the Sisters of St. Elizabeth's Hospital, has received assurances during the last week that their plans will have the

support of the physicians of Chicago. The physicians favor the hospital not only for the care of the afflicted, but also for the protection of the public from infection.

Treatment of Tuberculosis.—Professor Edwin Klebs read a paper on this subject before the Chicago Society of Internal Medicine, December 28th, in which he discussed the specific treatment by products of tubercle bacillus to reenforce the probably insufficient natural defenses of the body. He dwelt upon the action of tuberculin R. and tuberculocidin. He pointed out the insufficiency of specific treatment in tubercular persons with secondary infection. He said that achylia gastrica and thyroid atrophy were the effects of the action of tubercular toxins, and advanced experimental and clinical proofs.

Cerebellar Tumor.—Dr. D. A. K. Steele reported an interesting case upon which he had operated. The patient, a male, was thirteen years of age. After numerous skiagraphs had been taken it was thought the tumor was located in the left frontal convolution. As the condition of the boy was growing worse, and he was having involuntary evacuations from the bladder and bowels, and racking headaches, the left frontal lobe was trephined to relieve the intracranial pressure. The specialists who had examined the boy thought the data were insufficient to localize the tumor. In Dr. Steele's opinion no operation for the removal of the supposed cerebellar tumor was justifiable, as the boy was not expected to live and the recovery of such patients operated on for cerebellar tumor is unsatisfactory. However, the patient was subsequently operated upon, and a cerebellar tumor found on the left side instead of the right, as diagnosticated, it being situated in the left hemisphere of the cerebellum. The patient died forty hours after operation. The dimensions of the tumor were two inches in width, one and one-quarter inches in length, and one and one-half inches in its vertical diameter. It was situated close to the median line and pushed the right and middle lobes of the cerebellum to the right. Sections showed the typical structure of a glioma.

Medical Practise Act in Illinois.—On November 25th, Judge Tuthill announced a ruling holding that the State Board of Health of Illinois, under the Act of 1899, relating to the regulations of the practise of medicine in the State, has no authority to inquire into the actions of medical men who have received certificates entitling them to practise medicine in the State prior to the passage of the 1899 act, which went into effect July 1st. The interpretation of the law was made on the issuance of an injunction to restrain the State Board of Health from proceeding further in the steps taken by it to revoke the certificate of Dr. W. Frank Ross of Champaign, who was summoned before the Board to answer charges of unprofessional conduct made against him. The injunction petition filed by Ross stated that he was actively engaged in the practise of his profession in Champaign, and that the revocation of his certificate would be a serious injury to him. Attorney Allen, in behalf of Ross, contended that the 1899 statute, entitled "An Act to Regulate the Practise of Medicine in the State of Illinois," completely repealed all prior acts and by its express provisions limited the power of the board to only inquire into and revoke such licenses as would be issued after its passage. The State Board of Health by Attorney Cope argued to the court that the law should be construed in the light of the intention of the Legislature as expressed by all the acts passed on the question.

Vesicorectal Anastomosis.—Dr. Jacob Frank made a further report on vesicorectal anastomosis for the relief of exstrophy of the bladder and other pathologic conditions. He presented the gross specimen with the results of the bacteriologic and microscopic examinations made for him by Dr. Herzog of the dog killed before the meeting, held November 22, 1899. The external operation wound in the median line of the abdominal wall was completely healed. On opening the abdominal cavity the peritoneum, including the omentum, and all the abdominal structures appeared normal and free from any inflammatory change or reaction. The anastomosis between the bladder and rectum was firm and covered by a smooth, normal peritoneum. Before the anastomosis was examined any further, except for inspection *in situ*, the kidneys were lifted out of their position and inoculations were made from the pelvis of each kidney into glycerid agar tubes in the usual manner. The ureters on both sides were then resected loose down to their insertion into the bladder. The kidneys and ureters were normal in color and size. The kidney substance, on being brought to view by a median incision into the organ, was found to be normal. The anastomosed bladder and rectum on being removed were found to be normal. The bladder was very firmly contracted to its maximum. The mucous membrane of both bladder and rectum looked perfectly normal. The opening between bladder and rectum was small. The tissues which formed it were corrugated and perfectly normal in appearance. All the other organs of the animal were normal. The four test-tubes inoculated from the pelvis of the kidneys were kept in the brood-oven at blood temperature for six days; they remained absolutely sterile, and no growth of any kind developed. Histologic examination of the tissue of the cortex, as well as of the medulla of both kidneys, showed it to be normal. The pelvis of the kidney on either side was lined with normal epithelium. The subepithelial tissue of the pelvis showed a moderate amount of round-cell infiltration. The cells forming this infiltration were of the type of young connective-tissue cells and lymphocytes. Polynuclear leucocytes were not seen in the subepithelial tissue. Bacteria of no kind could be demonstrated either in the pelvis, the medulla, or the cortex of the kid-

neys. From the result of the microscopic, histologic, and bacteriologic examination, this dog was free from any infection of the kidneys and was to all appearances in perfect health.

GENERAL.

Students at Berlin.—At the Berlin University there are registered this winter 6478 students. This is the largest number ever assembled at a German university. Of the whole number 1346 are students of medicine.

Famine in India.—The present famine in Western India is destined to be far more disastrous than that of two years ago. The plague has already begun now, and the epidemic, going hand in hand with the famine, is destined to work distressing ravages.

$100,000 to Study Cancer.—By the will of Caroline Brewer Croft, who died in England nearly two years ago, a sum amounting to nearly $100,000 has been placed in the hands of the corporation of Harvard University, to be used in the investigation of cancer.

Smallpox among Indians.—There are serious epidemics of smallpox among the Indians in the Indian Territory, at Crow Creek Agency in South Dakota, and on other reservations. The Department of Interior at Washington has been telegraphed to from a number of agencies to forward vaccine points, but it is confronted by a lack of funds.

Extraction of Foreign Body from Bronchus.—It is reported that Dr. Schroetter of Vienna extracted, without cocain or other anesthetics, a piece of lead from a bronchus. The lead was located by means of the X-rays at the height of the fourth rib. A Kilian's bronchoscope was inserted and electrically lighted, and by the aid of this the lead was extracted with a specially constructed pincette.

Responsibility in Appendicitis.—C. Mansell Moullin, in a recent communication to the *Lancet*, delivered himself of the following ultimatum: "If in a case of inflamed appendix thirty-six hours have passed without definite improvement having shown itself, the responsibility for the consequences must, it seems to me, rest with those who recommend that an operation should not be performed."

Whisky in the United Kingdom.—The consumption of whisky during the year 1898 was the highest ever reached in the United Kingdom, according to the English temperance journals, being more than a gallon a head for every man, woman, and child. Compared with 1878, there has been an increase in deaths from chronic alcoholism of 82½ per cent. among men and of 145½ per cent. among women.

Mountain Toothache.—"Mountain toothache" or "jumping toothache" seems prevalent among the engineers and laborers on the Jungfrau Railroad, at a height of 8500 feet above sea-level. Several teeth are affected at a time, the attack lasts seven or eight days, and leaves the patient with a swollen face, which it takes another week to reduce. After that the teeth are acclimated and give no further trouble.

Favorable Opening for a Physician.—Opportunities now and then arise where the needed change of climate can be had by a physician without the sacrifice of time. A case of this kind has come to our knowledge in which a practitioner from the East, whose friends would deem it a privilege to send him patients, can make for himself a permanent or temporary home in Southern California, under the most attractive circumstances.

Plague at Manila.—Health officers have discovered within the walled city a native with pronounced symptoms of bubonic plague in a house in which two suspicious deaths have occurred. Active steps have been taken to prevent the spread of the disease. Secretary Root, after consultation with Surgeon-General Wyman, has decided to consign to the Marine Hospital Service the conduct of all quarantine matters relating to the army.

Hemorrhage through the Lachrymal Duct.—A case is reported in the recent issue of the *British Medical Journal* of a soldier suffering from Malta fever, who was attacked with severe epistaxis. After the ineffectual application of mild remedies, the nares were securely plugged; blood then appeared in each lower eyelid and trickled down the patient's cheeks, so great was the pressure and so little did the blood possess the power of coagulability.

The London School of Tropical Medicine.—The *British Medical Journal* regards the first season of the London School of Tropical Medicine as very successful. The number of students was twenty-eight; of these, fourteen were medical officers of the colonial service, the remaining fourteen being medical officers of the army and navy, or surgeons to railways, mines, etc., in the tropics. One student came from Germany and another from Belgium.

Dr. Osborne Acquitted.—Dr. Oliver T. Osborne, Professor of Materia Medica and Therapeutics in the Yale Medical School, was tried in New Haven on December 26th, on the charge of unlawfully disinterring a body. The doctor was acquitted. In rendering his decision Judge Studley stated that there was no question, from the evidence presented, that the doctor had been given permission to perform an autopsy upon the body in question.

McGill University.—At the regular monthly meeting of the corporation of McGill University at Montreal, on December 21st, it was decided to establish special courses in connection with the departments of legal medicine and public health and also a post-graduate course in sanitary state

medicine, adequate in both quality and scope to afford upon examination a diploma in public health corresponding to the diploma of public health of England or English universities.

Iowa Insane Asylum Scandals.—The Iowa State Board of Control, which is required by law to investigate the insane asylums in that State, has reported a deplorable condition of affairs in nearly thirty counties. Men and women are in some asylums indiscriminately herded together and no expert care or medical attendance is afforded them. The exposé of these conditions will no doubt bring about legislation abolishing county asylums and compelling the maintenance of insane persons in State institutions.

The Gold Cure Outrivaled.—Paris had hardly recovered from the sensation caused by Professor Metchnikoff's "discovery" of a new elixir of life, when it was announced on December 29th that Dr. Rappalier and Dr. Thiebault had found a "drink cure" in a serum extracted from a horse which (so the lay press states) had been previously alcoholized artificially. This serum, it is claimed, will produce in a patient an unconquerable distaste for alcohol. The Academy of Medicine of Paris has appointed a committee of investigation.

Proportion of Killed to Wounded.—During the three engagements that the forces of Lord Methuen have had in South Africa, the proportion of killed and wounded was approximately 1 to 5.3. This proportion is considerably below the average of previous campaigns, and is almost identical with the loss sustained by the Germans in the Franco-Prussian campaign of 1870-'71. What the proportion of killed and wounded among the Boers may be is not known. The Boers are using the Mauser rifle and the British are provided with the Lee-Metford.

Western Surgical and Gynecological Association.—At a meeting, held at Des Moines, Ia., December 27th and 28th, this association elected the following officers for the ensuing year: President, Dr. O. Beverly Campbell of St. Joseph, Mo.; first vice-president, Dr. A. C. Bernays of St. Louis, Mo.; second vice-president, Dr. J. R. Hollowbush of Rock Island, Ill.; secretary-treasurer, Dr. George H. Simmons of Chicago, Ill. Minneapolis, Minn., was selected as the place for holding the next annual meeting. Chairman of the Committee of Arrangements, Dr. A. W. Abbott.

Venereal Disease in the British Army.—A correspondent of the *Lancet* writes from South Africa: "I am sorry to say that the transports are dropping a lot of sick on arrival here, most reservists; and in some cases specific disease, acquired while in India or elsewhere, when serving with the colors, is very much in evidence. It is brought very much to notice that terrible ravages are made amongst the men by this dreadful disease, and the trouble is greatly accentuated when it becomes absolutely necessary to admit them to a hospital for treatment instead of getting them to the front as soon as possible."

Failure of Lustig's Plague Serum.—News comes from India that Lustig's plague serum has been well tested and the series of cases give no indication that the remedy has any efficacy. In this connection it is interesting to note that Dr. Guido Bacelli, demonstrator of public instruction at Rome, has been directing a series of experiments upon animals in which he claims to have established the fact that intravenous injections of bichlorid of mercury is a specific against bubonic plague. Professor Terni of the University of Massina has sent out to Portugal and Brazil to make known the result of these experiments with a view to adopting the treatment in the human subject.

Testaments and Tobacco.—It is curious how rapidly the medical and scientific side of the campaign against tobacco in all its forms appears to be subsiding. This is amusingly illustrated by the fact that first upon all the lists of comforts for the wounded supplied by the various funds in Great Britain come cigarettes and tobacco and pipes. Even the Red Cross Society has gone so far as to have special brands of cigarettes and makes of pipes prepared and stamped with its sacred emblem. And not a single medical or even clerical voice is raised in protest. Even the clergy are becoming positively friendly to the weed and one cheery evangelical sent to the Red Cross Society a large consignment of *Testaments and tobacco,* in about equal parts.

The Plague at Honolulu.—The transport "Centennial," arriving from Honolulu at San Francisco, December 28th, and the steamship "Aorangi," arriving at Victoria, B. C., the same date, reported the presence of the bubonic plague in the Hawaiian Islands. The outbreak occurred at Honolulu amongst the coolies recently arrived from Japan. Two to five cases terminated fatally. The Board of Health called for $10,000 to fight the plague, and immediately $25,000 was placed at its disposal. A system of fumigation was undertaken, the dead were cremated, and quarantine established. Later advices announce the death of a young girl from the plague, and the occurrence in opposite sections of the city of two cases of the disease in Chinamen. Honolulu is declared by the quarantine authorities an infected port. No ship leaving there can carry a clean bill of health. None of the army transports will be allowed to stop at Honolulu until quarantine is raised.

Death of Sir James Paget.—Sir James Paget, one of the most famous English surgeons of the century, died in London on December 30th. He was eighty-six years old. In 1836 he became a member of the Royal College of Surgeons, and in 1843 was made an honorary Fellow of that institution. Sir James made many contributions to science, among which are the "Pathological Catalogue of the Museum of the College of Sur-

geons," "Report on the Results of the Use of the Microscope," and "Lectures on Surgical Pathology." He contributed frequently to the "Transactions" of the Royal Society, of which he was a Fellow, and of other scientific bodies. In 1875 he was elected President of the Royal College of Surgeons, and from 1884 to 1895 was Vice-Chancellor of the University of London. Many other honors were accorded him during his lifetime. In 1871, in recognition of his humanitarian work and of his many discoveries in surgery, he was created a baronet.

The St. John's Ambulance Brigade.—This "first-aid" organization is responding nobly to calls for volunteers for South Africa. The first call for twenty-three men was responded to early in November. The second call for fifty-three men was responded to in *three days*, and the men embarked at once, and a third call for twenty-eight men was filled in five days. The first detachment was for service on board the Princess of Wales hospital ship, and the last for the Duke of Portland's Hospital. The English profession is keenly interested in St. John's Brigade, as the bulk of the instruction which its members receive is in the form of courses of lectures given by the leading practitioners of the various localities in which branches exist, and this means practically the whole of England. These "first-aid" lectures have been gladly given by medical men, and have proved an excellent means of giving the young people of the community a knowledge of the main principles of hygiene and nursing, and a slight practical conception of what scientific medicine, as distinguished from miracle-working charlatanism, really is.

Scientists Convene at Yale.—Many well-known scientific men, members of ten American associations, arrived at New Haven on December 26th from various parts of the United States. Some of the visitors were from Europe. Among the societies which met were the American Chemical Society, the Association of American Anatomists, the American Physiological Society, the American Psychological Association, the Anthropological Society, and the Society of College Gymnastic Directors. Among the less severely scientific papers presented was one by Dr. Jay W. Seaver of the Yale Gymnasium, on a comparison in anthropometry between the types of three women's colleges. Dr. Seaver announced that there are two distinct types of the American college girl, that of the East having the greater height and a "cutter" build of head and that of the West having much the greater girth of chest and larger lung capacity, with a "schooner" build of cranium. Dr. Seaver's paper elicited warm discussion, through which the writer's hopelessly soulless and unemotional temperament was made evident. Two very important papers from the medical man's viewpoint were read by Professors T. D. Aldrich of Detroit and Scripture of Yale. The former described a new anesthetic, chlorentone, a compound from chloroform and acetone, which can be administered internally. Professor Scripture reported progress in producing anesthesia by electricity. It is possible by this invention in its present stage to deaden sense so that pins may be inserted in the flesh without producing pain. The current has not yet been made effective in the presence of moisture, so as to make it available in dentistry.

Obituary.—In addition to the deaths of Sir James Paget and of Dr. Coues, several others have to be recorded. Dr. William B. Canfield, a resident of Baltimore, died in Roosevelt Hospital, in New York City, on December 26th, of a fractured skull, which injury he sustained by slipping on the sidewalk and striking his head against the curbstone. Dr. Canfield was forty-four years old.—Dr. Francis Bonynge died in Chicago on December 26th. He was wounded by the Boers in the famous Jameson raid, and served three months in Holloway jail because of his part in the affair.—Dr. Wickliffe Smith, surgeon of the 161st Indiana Regiment, was killed on December 29th, near Indianapolis, on account of the cold weather. He was muffled so that he did not hear an approaching train, and was struck and instantly killed. Dr. Smith was well known and greatly liked throughout Indiana.—Dr. Thomas C. O'Callaghan, one of the oldest physicians of Jersey City, died suddenly from apoplexy while visiting a patient on December 27th. He was born in Ireland in 1831. He was graduated from the New York College of Physicians and Surgeons in 1860.—The death of Dr. Frank Grover, a well-known physician of Newark, New Jersey, occurred on December 30th, under nearly similar circumstances. Dr. Grover was stricken with apoplexy while visiting a patient. He was removed to his home, where he died shortly afterward. He was fifty-five years old.—This very unusual obituary list closes with a notice of the death of Dr. Irwin R. Fisher, a prominent physician of Harlingen, New Jersey, who was found dead in his bed on the morning of December 31st. Death, which was due to natural causes, was ascribed by the county physician to "heart disease"—always a convenient diagnosis.

Influence of Lime on Malarious Soil.—M. Grellet, in a recent communication to the French Academy of Medicine, observes that up to the year 1840 malaria was rife among the inhabitants of Châtillon-sur-Loing; after that date it disappeared completely. Except in one particular no difference has been made in the agricultural methods employed, no drainage or sanitary works had been carried out, and no change had been made in the mode of living. Between 1824 and 1840 lime was applied to the soil for purely agricultural purposes, and by the time the whole plateau had been thus treated malaria had disappeared. Grellet maintains that the geographical distribution of malaria supports his contention that malaria is not found where the soil contains a sufficient quantity of lime. Lower Egypt, for instance, which, with its marshes, high

temperature, etc., might be expected to prove a hotbed of malaria, owes its general exemption to the relatively large amount of lime in the Nile water and mud. Still more striking are the differences observed in certain districts in France. La Beauce, on the right bank of the Loire, is free from malaria; across the river, la Sologne, on clay and gravel, suffers severely. The north (calcareous) coast of France is free from fever; the west coast, south of the Loire, is malarious—its soil is clay. No accurate observations have been made as yet on the quantity of lime necessary to kill the malaria parasite. At Châtillon-sur-Loing about 10 tons per acre were employed. At Lapeyrouse the amount used on granite soils and on clay were respectively about 2½ and 3½ tons per acre. M. Grellet makes no mention of the mosquitoes at Châtillon. The value of a process which at once checks malaria and improves the soil is obvious.—*British Medical Journal.*

Our Native Drug Plants.—The Secretary of Agriculture, Hon. James Wilson, has embraced the following paragraph in his annual report, which is of interest to the medical profession:

"The collection of native drug plants in the United States, considered from a purely financial standpoint, aside from medical and humanitarian aspects, involves the expenditure of millions of dollars annually. The commercial extermination of some of the most useful species is already threatened, and doubtless others would be found in the same conditions were the facts known. The price of one native plant, ginsing, our exports of which average more than a million dollars annually, has more than quadrupled in the past thirty years, so that its cultivation, as urged four years ago by this department, has now become profitable. It is clear from this and many similar cases that the native drug industry is capable of either decline or improvement, according to the way in which we handle it.

"The Pan-American Medical Congress has recently submitted to me a proposition to co-operate with this department in a technical and statistical investigation and classification of our native drug plants. By accepting this proposal we shall secure, in a research of which we have long felt the need, the cordial assistance and support of an influential association of learned physicians; we shall encourage each of the other American nations, all of which are represented in the Pan-American Medical Congress, to proceed with a similar investigation of their own medical flora; we shall furnish a basis for the remunerative employment of much land and many people, and we shall stimulate the great growth and growing trade in drugs between the countries of North and South America. I urge the appropriation of $10,000 to enable this department to co-operate in this investigation."

Death of Dr. Elliot Coues.—Dr. Elliot Coues died in Johns Hopkins Hospital from the effects of an operation on December 26th. From his father, Samuel Elliot Coues, who was a noted scientific man, he received his liking for natural history, which resulted in his development as an ornithologist. He was graduated from the Academic Department of the Columbian University in 1861 and from that institution's School of Medicine in 1863. Later his alma mater gave him the degrees of A.M. and Ph.D. He became assistant surgeon in the United States army in 1863 and held that rank until his resignation in 1881. Wherever his army duties called him he made exhaustive studies of the fauna and flora of the region, and he often set down the results of his investigations in valuable scientific papers. He held the chair of anatomy in the National Medical College from 1877 to 1883, when he was appointed professor of biology in the Virginia Agricultural and Mechanical College. Soon after his resignation from the army he began to investigate by means of scientific methods the phenomena of spiritualism and telepathy, with the result that he became a theosophist and a prominent associate of Madame Blavatsky. He was a member of the British Society of Psychical Research. In later years, however, he lost much of his interest in occult studies, probably because of his tardy apprehension of the emptiness and the trickery inherent in Madame Blavatsky's movement. One of the most important of his many literary labors was the contribution, during seven years, to the "Century Dictionary" of more than 40,000 words and definitions in general biology, comparative anatomy, and all branches of zoology. The range of his literary life was very great. He was the author of thirty-nine volumes, and he contributed over 1000 articles to various magazines and periodicals. He served six different scientific journals in editorial capacities, and his name was on the rolls of more than fifty American and foreign scientific societies. Dr. Coues was fifty-seven years old.

Medical Necrology During 1899.—Among the distinguished medical men who have passed away during the past year the following are worthy of special mention in closing up the medical accounts at the end of the year. Joseph Coates, professor of pathology at the University of Edinburgh, died January 24th. He was one of the men who twenty-five years ago realized that the scientific foundation of medicine was pathology; that if medicine was to advance in England as it had done in Germany, it must be by the cultivation of pathology. February 10th, Professor Laboulbene, professor of the history of medicine for twenty years at the University of Paris. When younger he was known especially for his work in pathology and entomology. February 21st, Professor William Rutherford, professor of physiology at the University of Edinburgh. February 25th, Sir John Struthers, emeritus professor of anatomy at the University of Aberdeen. March 10th, Sir Douglas Galton, M.D. May 27th, Professor Charpentier of the French Academy of Medicine. June 13th, Lawson Tait. Mr. Tait's death is the greatest loss medicine has

suffered, in English-speaking countries, during the year. His ground-breaking work in aseptic surgery, in tubal pregnancy, in ovariotomy, and in the surgery of the gall-bladder stamps him as the most original practical surgeon of our generation. July 31st, Dr. Daniel Garrison Brinton. Dr. Brinton served as a surgeon during the Civil War, though of late years he had acquired a worldwide reputation as an archeologist and ethnologist. August 20th, George A. Hendricks, professor of anatomy in the University of Minnesota, at the age of forty-nine. September 30th, Surgeon-General Sir Charles A. Gordon, K.C.B., of the British army. His work on enteric fever in India gave him high rank as a medical observer and hygienist. For his courageous and unselfish services during the siege of Paris, at which city he was a medical commissioner for the British government at that trying time, the cross of the Legion of Honor was conferred upon him. December 26th, Elliot Coues of Baltimore, and December 30th, Sir James Paget of London. The last two have more extended mention elsewhere in this issue.

Medical News from Seat of War.—Much comment is being made upon the contrast between the noble and friendly action of the American ladies in charge of the "Maine" and the resolution of "Senator Billy" Mason, thankfulness being expressed that it is the former which really represent the bulk of intelligent opinion in the State. The state of affairs in the Commissariat Department is not entirely satisfactory. Complaints continue to pour in, in private home letters, from enlisted men, of the wretched fare upon the transports en route for Africa, especially in regard to the meat, both salt and canned, the former of which was frequently condemned by the medical officers and the latter alleged to be most uninviting. One private alleges that he lived upon canned salmon and marmalade for ten days, paying out of his own pocket for them, and all writers agree that a large share of the men's pocket-money was spent for food, as high as two dollars being said to have been offered for a loaf of bread. Of course some of this must probably be discounted as due to Mr. Atkins's natural propensity to grumble at his food, especially when his appetite is "sicklied o'er" by *mal de mer*, but there is too much smoke of this sort not to have some real fire at the bottom of it. The English Admiralty has long had an unenviable reputation in this respect, since the scandals of the Crimea in fact, not from corruption or even incompetence in the ordinary sense, but from the paralyzing effects of its abject worship of red tape. A few of the complaints, however, are still more grave and involve the military authorities, as troops on the Orange River complain that, in spite of the presence of abundant stores of provisions, the actual rations served out to the men in the field are most scanty. Still, the defect cannot be very serious or widespread, as the health and general condition of the men at the front is universally reported as excellent. It is, however, a possibility to be borne in mind that the great fatigue complained of by the troops in and after an action, and which is declared an important factor in accounting for the large number of prisoners taken, may be dependent in some measure upon these alleged inadequacies of the commissariat. Extensive arrangements are being made for the reception of wounded and others invalided now at Netley Hospital, and specially fitted trains are provided for their conveyance from the docks directly to the hospital. The "volunteer" movement among general hospitals, sanatoria, and convalescent homes continues to spread, and offers of free accommodation for military invalids are coming in almost daily. One of the latest came from the London County Council, which, upon the urgent recommendation of its Parks Committee, has unanimously decided to turn the beautiful private mansion and park-like grounds at Golder's Hill, recently acquired as an addition to Hampstead Heath, into a temporary convalescent home for invalided soldiers. The expense of fitting and maintenance is to be borne by a committee of public-spirited residents of Hampstead, headed by several members of our own profession. The drain upon the insufficient army medical staff is again beginning to tell, and more civilian medical men are about to be enrolled to fill the gap. Professor Ogston of Aberdeen, whose able and outspoken criticism, at the Portsmouth British Medical Association, of the neglect of the Army Medical Department by the War Office, is going out to South Africa as an interested spectator; not, we need hardly say, in an official capacity or at the expense of the irate and offended War Office, although there is an apparently authoritative rumor abroad that he goes by request of the Queen.

CORRESPONDENCE

OUR LONDON LETTER.

[From Our Special Correspondent.]

BORIC ACID AND FORMALIN AS FOOD PRESERVATIVES—COW INSPECTION IN LONDON—TUBERCULOSIS CONGRESS—RESEARCH LABORATORIES—RISE IN LONDON DEATH-RATE—COMPLICATIONS AT LEICESTER—MEDICAL ARRANGEMENTS IN SOUTH AFRICA—MEDICAL MEN AND THE ROYAL SOCIETY—CANCER LABORATORY DONATION — INSANITARY FACTORIES — CONSUMPTION IN HOUSES—HEART MURMURS—MILLIONS FOR DRAINAGE—MODEL LODGING-HOUSES.

London, December 23, 1899.

Just as the departmental committee is holding its sessions upon the question of the use of preservatives in foods, and public attention is being directed toward the subject, a most timely paper by Dr. A. G. Faulerton, bacteriologist and lecturer upon hygiene at the Middlesex Hospital, has appeared in the *Lancet*. This

is the report of an elaborate original investigation into the effects of formalin, boracic and salicylic acids upon the general health, the processes of digestion, and the solubility of the food treated with them. He comes to the reassuring conclusion that in the amounts usually present neither formalin nor boracic acid have any appreciable effect upon either the general system or the digestion, except possibly in the case of delicate children or invalids who are on an exclusive diet of the food. Their use should, however, be strictly regulated, only such as are approved by the Local Government Board being permitted at all, and these in proportions not to exceed a specified maximum. Lastly, all "treated" or "preserved" foods should be clearly labeled or otherwise indicated as such. With these conclusions most of us will agree, especially as to the advisability of having rigid examinations of food and condemnation of all specimens containing more than the proportion allowed. But as to whether the labeling of the milk, butter or cheese as "treated" could ever be anything more than a "counsel of perfection" seems seriously doubtful. Such a label in the present state of public sentiment would simply condemn the goods at sight and ruin their sale. Permission to use on these terms is tantamount to an absolute prohibition and would prove practically as difficult of regulation and enforcement. We are fully justified in the radical step on the ground that such additions open the way for the covering up of all sorts of carelessness and uncleanliness in the original handling and collection of milk and cream.

The Public Health Committee of the London County Council report that their inspectors have examined 5144 cows in London dairies and found 680 or 13 per cent. presenting clinical symptoms of tuberculosis. They recommend that dairy cattle in the London cowsheds should be examined regularly at least every three months by veterinary surgeons, and suspected cows at more frequent intervals. This inspection will, however, never be complete or really effective until it includes the systematic use of the tubercular test.

The National Association for the Prevention of Consumption, since its inauguration last spring under the auspices of the Prince of Wales, has spread rapidly until it now has branches in almost every part of England. Eminent members of the medical profession have been most active in promoting its interests and it is now proposed to hold a congress in London in furtherance of its aims in the spring of 1900. The Prince of Wales has accepted the presidency at the gathering and the council of the association, of which Sir Wm. Broadhurst is chairman, are working on the liminary arrangements.

The research movement is steadily spreading in London. Following close upon the establishment of a cancer laboratory at the Middlesex Hospital, the Governors of the Westminster Hospital have announced the equipment of a clinical research laboratory with modern appliances and a "pure" pathologist at its head, upon the lines, as they themselves complacently remark, which have proved so successful at Johns Hopkins. Congratulations are pouring in upon them from all sides and we must all cordially unite in these but cannot forbear a friendly comment of surprise upon one feature of the scheme. The Governors take special pains to announce that the superintendent is to be a professed pathologist and freed from dependence upon general practise and that hence his salary should be on a proportionate scale, wherefore he is to receive the sum of $1,250 a year with certain fees from lectures in the medical school at the hospital. It is to be hoped that these lecture fees are distinctly liberal, else it would hardly appear to transatlantic eyes as if the professed pathologist was as completely freed from dependence upon practise or other sources of income as might be desired.

The sudden change in the hitherto mild weather to dense fog, followed by raw frosts and light snow, has had a striking effect upon the London death-rate, sending the unusually low rate of a week ago of 17.5 per 1000 sharply up to 22.4 per 1000. The increase was chiefly in deaths from diseases of the respiratory organs which leaped from 430 to 548, or 112 above the corrected average for this week of the year. A similar effect has been produced among our cousins at the Zoological, no less than two out of the three surviving chimpanzees having joined the majority by the way of bronchopneumonia.

There is still trouble at Leicester. When the Guardians made their submission to the Court Mr. Justice assumed a most astute attitude of reserve and declined to dismiss the charge of contempt against them until he was assured that their compliance was genuine and the vaccination-officer appointed a suitable man. And his suspicions have been abundantly justified already, for the Local Government Board have declined to confirm the officer on the ground that he had been fined some years before for failing to have his children vaccinated and was even now a defaulter under the Act, as his youngest child, although three years of age, was still unvaccinated. They had also found that he did not propose to prosecute defaulters except *with the concurrence of the Guardians*, and hence his appointment was practically a farce. Wherefore the Guardians are advertising for another candidate and are hastening to submit their apologies to the incensed High Court.

The medical news from South Africa for the past week has been as scanty as the military, owing probably to the strict censorship exercised over all the telegrams by the authorities. So far as it goes, however, it is most satisfactory. The wounded are doing wonderfully well; little dysentery or typhoid and no crowding whatever in the hospitals. The only serious anxiety is as to the condition of the troops and civilians shut up in Ladysmith and Kimberly, especially

the former, where, as intimated in a former letter, typhoid is a regular seasonal occurrence to a greater or less degree.

The profession is again strongly and most creditably represented upon the blue-ribbon list of English science, the staff of the Royal Society. Lord Lister has just been elected to succeed himself as President. Sir Michael Foster is again Hon. Secretary, while upon the Council are Profs. Herdman and Halliburton of physiological and pathological fame, and Sir Samuel Wilks, late President of the Royal College of Physicians.

The public is getting decidedly interested in cancer. Only three days ago the Governors of the Middlesex Hospital announced to the press their intention, which they had been maturing for some months, of opening a cancer-research laboratory in connection with their new cancer wing. They mentioned the amounts to be expended upon equipment and maintenance, remarking merely that subscriptions would probably have to be asked for. Within forty-eight hours they received in one donation from Mr. Arthur W. Davis the sum of $5,000 sufficient to cover running expenses upon the scale contemplated, for nearly two years.

Even in England sanitary legislation gets "hung up" sometimes. Only this week a delegation of cotton-cloth workers representing 80,000 operatives called upon Sir Kenelm Digby at the Home Office to complain of the insanitary condition of their factories. The artificial moisture required in the weaving-sheds is kept up by sprays of impure water, the percentage of carbon dioxid created in the processes is far in excess of the legal maximum, and the rooms are excessively overheated—the only such in England if this be the case. An order in court prohibiting these abuses was issued twenty months ago, but no effect whatever had been produced yet. Sir Kenelm Digby replied that it took time to put such orders in force—which was tolerably obvious—but that the office would at once move in the matter.

Sir Richard Thorne-Thorne, in his address upon "The Prevention of Tuberculosis," before the London Medical Society, summed up his view of the method of spread of tuberculosis in the sentence, "Consumption runs in houses—not in families." He called attention to the fact, too easily overlooked in these bacillophobe days, that the chief factor in the huge fifty per cent. reduction of the tubercular death-rate had been drainage of the subsoil and ventilation of houses, and that two-thirds of it had been effected before the bacillus was discovered.

An interesting case of heart murmur was demonstrated by Sir William Broadbent, at his consultation at the Polyclinic this week. This was the extracardial "rub," due to the friction of a small thickened patch upon the pericardium—a "pericardial corn," as Sir William graphically described it. These patches are quite common, occur without any inflammatory process, and last for years, or even a lifetime without changing or giving rise to any symptoms whatever except the murmur. Their chief distinguishing character is that the murmur disappears or diminishes under firm pressure. The lecturer stated that many young men are needlessly rejected at army entrance-examinations on account of these soft systolic murmurs, which have really no practical morbid or prognostic significance.

The immensity of the sanitary problems of London may be imagined from the action of the progressive London County Council, or "L. C. C." as it is always spoken of, this week, when it was decided to expend upon a main drainage scheme alone the sum of $7,500,000, and this is only the first instalment upon a project estimated to ultimately require some $15,000,000. But the design is as superb as its cost, for it achieves the complete freeing of the Thames from both sewage and surface water, and the delivery of these by great conduits into the estuary several miles below the city. Even this, however, will only solve the problem temporarily, on account of the rapid extension of the river suburbs down the shores of the estuary, and the undesirable effects of these enormous quantities of sewage upon the lower reaches of the river, which is already beginning to be noticeable. Sooner or later the problem of the direct destruction or purification of the sewage either by chemical, combustive, or "natural" farm methods will have to be faced.

An experiment which will be watched with great interest by all sanitarians was resolved on this week by the London County Council. This is the erection of a model lodging-house upon the Rowton plan, as a means of relieving one form of London's overcrowding. These "Poor Man's Hotels," as they term themselves, are the admirable device of a philanthropic peer, Lord Rowton, and are huge well-warmed and lighted buildings where, for the modest sum of 12½ cents a man can secure not only a tiny cubicle and cot for the night, but a bath, a shave, the use of a reading-room and smoking-room. A dining-room and series of cooking-ranges, with utensils, are also free, and at a buttery portions of food of all sorts may be bought for from 1 to 6 cents, and then cooked by the "guests" themselves. There are now three of these in London.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE—SECTION ON SURGERY.

Stated Meeting, Held December 11, 1899.

Charles N. Dowd, M.D., Chairman.

A Case of Prostatectomy was presented by Dr. Alex. B. Johnson. The patient, sixty years old, a silk weaver, suffered first from difficulties of urination some five years ago. Then his urination

became painful and frequent, especially at night. During the last few weeks before his admission to Roosevelt Hospital in October, 1899, he had been compelled to pass his water ever ten minutes. He had been catheterized frequently without affording him very much relief. He had never used the catheter himself. His peripheral arteries were atheromatous; there was no cardiac lesion present. His urine was normal in quantity, fetid in odor, but not ammoniacal, contained pus, but no casts. There were five ounces of residual urine. An enlarged prostate, apparently symmetrical, could be felt per rectum. When the patient first came into the hospital his pulse was 120. There was a constant desire to urinate, which was not relieved by catheterization, and despite the fact that he was catheterized every couple of hours for five days his condition was not improved. He was not only ready then but anxious for any operation that promised to give him relief.

Under ether anesthesia an incision two inches long was made at the median line just above the pubis. The prostatic collar could be felt very plainly projecting into the bladder and there was a large prominence behind it. A transverse incision was made just in front of the anus and then, by blunt dissection, mainly with the finger the enlarged prostate was easily shelled out. The median lobe came away with the torn mucous membrane of the membranous portion of the urethra. The median suprapubic incision was closed, a large catheter was passed in the wound in the perineum, and the latter packed. There was not any shock, nor pain after the operation, nor symptoms of even slight septic infection. The urine drained through the packing, which was of sterile gauze, and had to be changed frequently for the first couple of days. For the first twenty-four hours the discharge was somewhat better. After forty-eight hours iodoform gauze was substituted in the dressings, and a gradually decreasing amount was used. The catheter was allowed to remain in for the first eight days. After this a 32 French sound was passed.

His first voluntary urination took place on the eighteenth day. Faradic electricity was used in order to increase the muscular tone of the overstretched bladder. It was applied by means of a metal electrode inserted into the rectum and a sponge electrode over the pubis, and proved very effective. There was a gradual increase in strength of the stream and in the amount of urine passed by the urethra, with a decrease in the amount of urine passed by the perineal sinus.

At the present time, two months after the operation, he weighs twenty-five pounds more than he did before it, is able to retain his urine for long intervals, urinates freely at will, and his urine is normal. There is still a slight sinus in the perineum, through which a certain amount of urine trickles at times, but it is visibly growing less and less in amount from day to day, and the sinus is rapidly closing up. The impression obtained from an operation like this is that it is much easier to do a prostatectomy than it has usually been thought. The speaker said that if he were to do another operation of the same kind there is one improvement in technic that he should endeavor to put into practice. He would not tear through the membranous urethra, but would shave the prostrate from along side of it, after shelling out the lateral lobes. This would perhaps cause more hemorrhage at the time of the operation, but it does not seem that this would be difficult to control, and convalescence would certainly be very much shortened by this procedure.

Prostatectomy and Urethral Resection.—Dr. Eugene Fuller presented two cases of prostatectomy and one case of resection of the urethra. The first patient, a man sixty years of age, had followed the sea for many years. He had all the prostatic symptoms. He had been under treatment at a metropolitan hospital, where perineal drainage had been tried, but absolutely no attempt was made to do anything for the prostatic condition. The result was a urinary fistula in the perineum, but no relief of his symptoms. The patient had atony of the bladder, his urine was extremely foul, and his symptoms were so severe that he was ready to undergo any operation which promised relief. Prostatectomy was surely indicated.

An attempt was made to do the prostatectomy through a suprapubic incision, but the peritoneum was found to be so involved in chronic inflammatory adhesions that it was impossible to expose the bladder sufficiently to make the ordinary incision. The transverse incision suggested by Trendelenburg might have been tried, but it so often proves the occasion of bulging in this region afterward that it was not deemed advisable. The operation had to be performed through the perineum. Operative procedures were much complicated by the fact that the old sinus had to be cut out during the course of the operation. The prostate was so large that it was hard to deliver through the perineum, and it was only when one of the heavy straight forceps usually used in peritoneal work was employed that the prostate could be grasped and brought out. No sounds were used after the operation. They are of no benefit as far as can be seen and they cause traumatism that should be avoided if possible. A resection of the urethra was made after the removal of the prostate, and a catheter was allowed to remain in for some time. At the present time the patient is able to pass a good forcible stream of perfectly normal urine, has none of his old symptoms, and can retain his urine for reasonably long intervals. Dr. Fuller then showed a second case in which there had been inflammatory thickening all around the prostate from the presence of gonorrhea, prostatitis, seminal vesiculitis, and other complications that had caused a massing together of all the tissues in the neighborhood of the prostate. The bladder was atonied—a quart of water might be injected into it without causing a reaction for its expulsion. A hemorrhage into such a bladder would be very dangerous, and no packing around the catheter would suffice to stop it.

The prostate was removed through a suprapubic incision, and a second opening was made through the perineum for drainage. Where atony of the bladder has existed for some time the only thing that gives any assurance of recovery from vesical symptoms is to set the bladder absolutely at rest for a time. Otherwise bothersome recurrence of symptoms will surely take place.

Resection of Urethra.—Dr. Fuller's third patient suffered from stricture through which it was extremely difficult to pass a catheter, and it had finally become practically impossible after a number of false openings had been made. Instead of spending half to three-quarters of an hour trying to pass a sound, it seemed more advisable not to keep the weakened patient for a long time under ether, but to do the operation without a guide. The urethra was resected, the ends carefully sutured together, and at the present time the patient is able to pass a perfectly good stream. No instruments were used to dilate the urethra after the operation, and it does not seem advisable at any time to use them. They always do more harm than good.

Prostatectomy at Seventy-one Years of Age.—Dr. Forbes Hawkes presented a patient, seventy-one years of age, who had had two attacks of retention of urine during the past year, the last one being a very severe one. His prostate proved to be very much enlarged and his urethra was over twelve inches long. Sixteen ounces of urine were removed after considerable difficulty. The patient was very willing to undergo a radical operation because he had suffered a good deal and feared the result of another attack of retention. His inguinal glands were enlarged, and it seemed as though on palpation through the rectum some enlarged retroperitoneal glands could be felt. The case looked like one of carcinoma of the bladder, and an unfavorable prognosis was given.

A suprapubic incision was made and then an incision through the vesical walls over the enlarged lateral lobes and prostate. These were rather easily shelled out. The median prostatic lobe, which was also enlarged, was then worked out through the space furnished by the previous removal of lateral tissue. Into the pouches that were left drainage-tubes were put down, in order to carry off any accumulation of blood. The catheter was retained for some days. Everything healed very kindly and the patient's present condition two months after the operation is excellent. He goes to bed at nine and does not have to get up until seven. His control of his urine is practically perfect. When he sneezes a drop or two is sometimes forced from the urethra.

In this case the enlargement of the prostate was much more into the bladder than downward into the rectum. By palpation in the rectum the prostate did not seem much enlarged, and seemed to be regular and symmetrical. It proved, on removal, to be very irregular and nodular, the enlarged lateral lobes overlying the median lobes and pressing against one another. The tumors after the enucleation weighed five ounces.

Floating Cartilage of Knee-joint.—Dr. B. Farquhar Curtis presented a patient showing the result of an operation for the removal of such a cartilage. The patient, a young man, had had no symptoms until June, when as the result of dancing he suffered from traumatic synovitis, with effusion into the joint. In September, from even a slighter cause, he had another such an attack. An irregular body was found projecting beneath the skin at one side of the knee and was cut down upon and removed. It proved to be a bit of purely hyaline cartilage attached by a pedicle to the upper part of the capsule of the joint. The healing was rapid and at the present time there seems every hope that there will be no further attacks.

Dr. Lloyd presented a case in which the patient, after jumping, had been compelled to limp, and noticed a clicking in the joint. He felt something movable there. The joint was opened and four bits of floating cartilage were found. One about the size of an almond kernel, and three others the size of peas. On the tenth day the splint was taken off and the patient had good motion. There is still a little pull on the ligamentum patellæ, but motion is good and there has been no recurrence of any symptoms.

Cystoscope of Nitze and Caspar.—Dr. Willy Meyer demonstrated the ingenuity especially of Nitze's instrument, showing how the loop for seizing intravesical tumors was manipulated, and how it might readily be changed into an electric cautery. Cauterization of these tumors is possible notwithstanding the presence of water in the bladder, because the loop of wire buries itself in the tissues of the tumor, and so is protected for the moment from contact with the water, and the consequent cooling.

With this instrument Dr. Nitze has operated on thirty patients. They were operated on as office cases, and did not require being put to bed. Frequently they were allowed to go to the theater or to a dinner-party the same evening. The tumors were removed piecemeal, as many as fifteen sittings being required for some of them. Death did not occur and there were no alarming symptoms. At times there was severe hemorrhage, and the clots had to be washed out with an aspirating instrument. The major part of the tumors removed were papillomata, and proved to be benign. The cases were followed for a year and a half afterward, without a single recurrence as far as could be ascertained. Dr. Nitze differs from Rokitansky with reference to the character of these tumors, and considers that many that used to be considered malignant are really benign and when removed will not return.

Bottini Prostatic Cauterizer.—Dr. Meyer demonstrated this instrument and showed how readily it could be employed. He has used Bottini's method of treating prostatic hypertrophy in twenty-three patients during this last year and a half, and has had no recurrences. Bottini himself, whose experience extends over twenty-four years, says he has never seen any recurrences. Operations for prostatic trouble so far have either

been offensively mutilating, or have been so severe that patients have refused operation until pyelonephritis or other serious complications made even simple operations very grave. It would seem that this comparatively easy procedure of Bottini's will tempt patients to allow themselves to be operated on sooner and so anticipate the severer troubles. This would seem to be particularly the field for Bottini's operation. With regard to the cauterizator there is one case in particular reported by Bottini, which is very striking. A boy of sixteen, who had been incontinent of urine for some fourteen years, was completely cured by a single cauterization of the neck of the bladder.

It would seem that there is a field for it in certain cases of chronic gonorrheal prostatitis where deep injections and massage, and every other mode of treatment has failed.

In discussion, Dr. Bolton Bangs said that the ingenuity of Nitze, as displayed in the cystoscope that he has given the profession, is certainly to be admired. It is undoubtedly a welcome addition to the armamentarium of the surgeon, but it is very doubtful if it will accomplish all that its inventor hopes for. Tumors of the bladder are, unfortunately, oftener malignant than benign. Perhaps the operating cystoscope will be of use for cases of recurrence, when patients will be more ready to submit to this form of intervention than to operation. As to the Bottini cauterizator, he said that he had not had any experience with it. The Bottini incision has certainly come to stay, but it is necessary to select the cases in which it will surely be useful. In some cases, notwithstanding long and broad and deep incisions, it had failed to give anything more than temporary relief. In soft prostatic enlargement, where the glandular elements predominate, it seems to do good. But in the fibroid enlargement of the prostate it has been less successful.

Dr. Samuel Alexander said that there are two questions which must be considered in all treatment of enlargement of the prostate: First, what are the causes of the vesical and urinary symptoms, and, secondly, what operation will give relief? There is primarily a set of permanent obstructions. These are due to overgrowth of the prostatic gland itself, and of accessory prostates. And then there is a secondary temporary obstruction due to edema of the prostate and venous stasis within the gland. In any case it is the disturbance by the tumor of the muscle fibers of the bladder which prevents the proper emptying of that viscus. Tumors, especially of the middle lobe of the prostate and of the accessory prostatic glands existing beneath the mucous membrane of the trigone, cause this disturbance of muscular action. Hence, atony of the bladder develops from overstretching in the hopeless effort to empty the bladder under such unfavorable circumstances. The only operation that will remedy this interference with muscular action is the removal of the enlarged prostate that causes it. Bottini's operation only removes the obstruction; it does not allow the vesical fibers to resume their want of function. Besides this, it does not drain the bladder and so give it the time for an absolute rest, which is the only thing that can restore it to its normal condition. Bottini's operation gives but temporary relief, and then leaves the tissues in an extremely unfavorable condition for any radical operation to be undertaken afterward. It would be too bad if the desire for novelty should replace scientific judgment in so serious a matter as this, and a protest should be raised against the present movement in favor of Bottini's methods.

Dr. Otis thought that Dr. Nitze's very ingenious instrument will very probably never be of any practical service except to aid in the catheterization of the ureters. It requires too much skill in itself, and the opening of the bladder has become comparatively so safe an operation in our day that it is evidently more advisable to do the operation under the direction of the eye and hand than with the doubtful operating cystoscope.

Dr. Willy Meyer, in closing, said that Dr. Nitze claims that his method should be used only for benign tumors, which, he says, are more frequent in the bladder than is usually thought. It is not probable that Bottini's method will do away with all necessity for operative work on the prostate; still the hope may be cherished that patients who are developing symptoms of prostatic trouble will be persuaded sooner to accept this method for relief of their symptoms than they would the older and more severe operations.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held November 25, 1899.

William B. Coley, M.D., Vice-President, in the Chair.

New Electro-Static Current.—Dr. William James Morton read a paper on this subject with considerations of its place in electro-therapeutics. He said that the history of electricity in medicine in this country does not go back very far. In 1881 he brought the first influence electric machine to this country from France. At that time Dr. Knight had a small static electric apparatus which was the only one of the kind in New York City. Now, of course, the number of static machines in use runs up into the thousands. Fashionable drugs come and go, but static electricity has continued to gain in popularity until now it is one of the most generally used of therapeutic agents.

Effects of Static Electricity.—The long spark or the shorter finer one producing the prickling sensation is used. The therapeutic advantage of the spark comes from its percussive effect. This effect is produced not alone on the surface, but also on the tissues beneath the skin. The molecular perturbation produced in muscular tissue causes a decided reaction in normal metabolism. Besides this there is now no doubt that electricity

applied to peripheral nerves acts upon the nerve centers. Hodges' observations show that peripheral excitation produces changes in nerve-cells, causing decrease in the size of their nuclei and variations in the appearance of their protoplasm.

Besides the ordinary static electricity with discontinuous sparks there are two forms of current electricity from the static machine which may be employed. In the one the patient on an insulated stool receives the current from a static machine until fully charged. Surplus current then either passes off into the air or may be taken from the patient with the production of sparks just as if he were touched by one pole of the machine when in contact with the other. The effect of the current of electricity passing into him is essentially tonic in action and while stimulating is not in any sense irritative. On the contrary there is a distinct soothing effect produced especially on excited nerve-tissue and this with its stimulating action has an excellent effect on chronic neurasthenic and other neurotic conditions. Painful affections that are not acutely so but long enduring and productive of a great deal of annoyance are especially benefited by frequent treatments of this kind.

There is a second form of static current that is still more interesting, because more effective and especially more soothing and anesthetic than the preceding one. In taking this the patient is seated upon the insulated stool as before and one of the poles of the static machine is grounded, an electrode attached to the other pole being placed on the patient wherever the soothing and stimulating properties of this current are required. In this current the patient forms a part of the displacement circuit of Clarke Maxwell, or, to put it in what is now a more popular form of expression, the patient is the sending pole of a Marconi wireless telegraphic circuit.

Spark-Gap Current.—The electric wave or spark-gap current is able to produce physiological tetanus of muscles with the least pain possible under the circumstances. Not only that, but its absolute effect is greater than that of the static current. Experiments have shown that a muscle can be made to lift a dumbbell without pain by exciting it with this current, when to produce the same effect with the other current will cause considerable pain. This spark-gap current has a general and local effect. In general it is tonic in quality, accelerates combustion and oxidation in the tissues, and this improves metabolism and hastens excretion. D'Arsonval found that under its use there was produced in the tissues more water, more carbon dioxid, and more urea than under ordinary circumstances. The salient fact in its use is this notable increase of metabolism.

Therapeutic Applications; Locomotor Ataxia.—So much has been claimed theoretically for electricity that only practical results really deserve consideration. In progressive locomotor ataxia of the first and second degree the use of the static machine will arrest the progress of the disease, improve the co-ordination, lessen the bladder symptoms, decrease the pain, diminish the number of crises, and relieve sexual and urinary symptoms. There is distinct improvement from the very beginning of the treatment. In cases where a spark was not felt at the beginning of the treatment it could be distinctly felt at the end of four minutes, while at the end of a quarter of an hour sensation had returned to such a degree that the same length of spark could be no longer tolerated. As the sensations improve in locomotor ataxia the co-ordination becomes better. Patients themselves are more satisfied with the treatment because of its effect upon their pains as well as upon their sexual potency, and also for the confidence it gives them in their power of co-ordination.

Here is a patient who has suffered for nearly ten years from tabes, with lightning pains which were so severe and so frequent as to make life almost unbearable. His co-ordination was so much affected that he could walk around only with the aid of two canes. His confidence in himself even under these circumstances was so slight that he scarcely ventured to go on crowded streets or to cross the street when vehicles were approaching. His general condition was very much debilitated by his frequently recurring pains and by various visceral crises. As can be seen at the present time, he is able to walk well with but one cane, or can even dispense with that and still walk reasonably well. He has regained confidence in himself and is able to go about the streets without fear. He goes up and down stairs without difficulty, and his old sensation of always walking on carpet has almost completely disappeared. He is able to turn rapidly, and can guide himself confidently through a crowd. He has been so much improved by three months' treatment with static electricity that he now considers himself in very tolerable condition. He is very proud and very satisfied with the results that have been secured. The case strikingly illustrates how much can be done for tabes even in its most seemingly hopeless condition by careful treatment with this method.

Rheumatoid Arthritis.—A second group of cases in which electricity works almost incredible wonders is rheumatoid arthritis. This affection is usually considered incurable. During the past few years some thirty cases have been under treatment at the Post-Graduate Medical School and Hospital. Many of them have been cured, and in all of them the progress of the disease has been arrested. There is present this evening one of the most satisfactory cases, a private patient who, after having been under electrical treatment in France, was told that it was possible for her to receive the same sort of electrical treatment at home, and was referred to him. She had the swollen, stiff joints of the advanced preliminary stage of rheumatoid arthritis and was rapidly becoming absolutely helpless. She was not able to break bread in her fingers, and practically all of her joints were very stiff. As may be seen, three months of treatment has completely cured her, and she was able to dance at the last Assembly ball.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVI. NEW YORK, SATURDAY, JANUARY 13, 1900. NO. 2.

ORIGINAL ARTICLES.

GONORRHEA; ITS DANGERS TO SOCIETY.[1]

BY ALBERT NEISSER, M.D.,

OF BRESLAU, GERMANY;

DIRECTOR OF THE ROYAL DERMATOLOGICAL HOSPITAL AT BRESLAU AND PROFESSOR OF DERMATOLOGY IN THE ROYAL UNIVERSITY OF BRESLAU.

THE object of the article which I have written at the request of the organizing committee of this international conference is to present a brief review of the dangers that are known to result to the human race from gonorrheal affections. The impression continues to obtain in non-medical minds that the only venereal disease to be feared is syphilis. It is to contravene this popular notion and to make clear that recent experience and advances in scientific medicine have demonstrated that, for the female sex at least, gonorrheal infection brings with it far greater dangers to health and to capacity for work than does even syphilis that the present paper has been written. The dangers of the disease are so much the more to be feared since, during recent years, despite the great advances which have been made in medicine generally, the therapy of gonorrhea has not developed to a degree that would enable us to give assurances of cure as we can usually promise from the treatment of syphilis.

Unfortunately, it cannot be denied that something of this lack of success in the treatment of gonorrhea is due to the fact that many physicians retain old prejudices. "It is only a little clap," they say, and they do not demand the same stringent and careful regulation of life as they do when there is a question of syphilis. The old school physicians, moreover, are so wrapt up in old-fogy notions of treatment that they have neglected to give sufficient attention to the modern therapeutics of gonorrhea, and especially to the prophylaxis of complications.

Gonorrhea is in all civilized countries an extremely widespread disease. It is, perhaps, with the exception of measles, the commonest of the infectious diseases. The exact statistics as to its occurrence are not easy to obtain, since most of the cases of gonorrhea, even when they do come to medical men for treatment, and are not treated by quacks, apothecaries, and sympathetic companions in misery, form a part of the private practise of physicians.

Proportionately only a very small number of those who suffer from the disease come to hospitals, from which, of course, statistics are obtained. Especially incomplete are the statistics of the occurrence of gonorrhea in women. In most of the cases the early stage of infection in the female is either not noticed by the patients themselves or is falsely interpreted, and so escapes medical handling, and thus affords no statistical material. In all the stages of the infection, after the first acute inflammatory reaction has pased, the symptoms are so slight that recognition of the disease is nearly always impossible, unless, indeed, serious affections of the internal genital organs have already declared themselves.

It remains, then, to give a summary of the statistics such as can be obtained from hospital reports and the like. Naturally the numbers are much below the true incidents of gonorrhea even among the lower classes from which the patients of our local public institutions are mainly recruited. A good approximate idea of the prevalence of the disease is furnished by the statistics of the cases of gonorrhea in the various armies. We have here, on the one hand, a large number of men of about the same age, who live under almost similar circumstances and in whom the most careful inspection succeeds in bringing without doubt the very largest part of venereal diseases to treatment and statistical tabulation. As to the differences in the prevalence of the disease in various armies I have nothing to say here.

	Total No. of Soldiers.			Gonorrhea—Absolute Number.		
	1891-92	1892-93	1893-94	1891-92	1892-93	1893-94
German Army	434,680	439,161	467,333	7,200	7,511	8,364
Austrian Army	284,743	289,460	298,035	9,150	8,598	8,838
Belgian Army	43,184	44,549	47,045	912	920	995
French Army	474,067	464,778	467,781	14,848	14,544	14,865

	Gonorrhea—Per Capita Percentage.			Gonorrhea—Percentage of whole No. of Venereal Diseases.		
	1891-92	1892-93	1893-94	1891-92	1892-93	1893-94
German Army	15.8	15.7	16.6	54.4	53.1	50.5
Austrian Army	32.1	29.6	29.6	53.5	51.6	49.0
Belgian Army	21.1	20.6	21.1	65.4	63.1	61.3
French Army	27.9	27.8	28.3	63.6	63.7	64.7

With reference to the civil population the following statistics seem of interest: During the year 1896 I sent a circular to all physicians practising in Breslau, and to all the institutions, asking that an account be kept of how many cases of venereal diseases were treated during the course of a single year in Breslau. Precautions were taken that the same patient should not be counted more than once and that patients who were only passing through Breslau should be separated from actual inhabitants of the city. Unfortunately only 81½ per cent. of the physicians to whom circulars were sent furnished replies.

[1] An answer to the second question of the Conference for the Prophylaxis of Venereal Disease, held at Brussels, September, 1899. Translated by Dr. James J. Walsh for the MEDICAL NEWS. All rights reserved.

In spite of this the figures, I think, are not entirely worthless.

Altogether, 7685 persons were reported as suffering from venereal infection or complications of venereal infection. Of these, 6940 lived in Breslau. Of the inhabitants of Breslau, 3284 suffered from gonorrhea. This would make 8.7 per cent. of the population of the city in the year 1896.

This figure naturally does not give a true picture of the actual occurrence of the disease among the population, for one-fifth of the physicians sent no reply. Even if among those who made reports we consider that practically all those who had fresh cases to treat were included, yet, on the other hand, reports of gonorrhea in the female to a very large extent are wanting. This is clear, since of the 3699 reported cases of gonorrhea only 591 were in females. Of these, 238 were prostitutes and 85 were in women whose gonorrhea was only recognized because their newborn children developed gonorrheal ophthalmia. Finally, it must be remembered that the reports only concern such cases as came under treatment during the present year, so that the very large number of cases in which the disease was acquired some time ago, or in which residual complications exist, although they have not come under medical treatment in the present year, are entirely lacking from the statistics. Further evidence of the amount of error can be gathered from the fact that only 85 married women are reported as suffering from the disease, while 398 married men come into the statistics.

The proportion of gonorrhea to other venereal diseases is 47.3 per cent. of the whole number; syphilis represents 42.2 per cent., and soft chancre 10.4 per cent. It is very natural to think that in these statistics it is especially the number of cases of gonorrhea which corresponds least to the actual number, for it is sure that patients with ulcerative or syphilitic lesions come to a medical man much oftener than do those suffering only from gonorrhea. This is true in particular in the female sex.

Practically the same figures as we have for Breslau come to us from Copenhagen. In the year 1894 a special census in this matter was made, physicians being obliged by law to send in an account of all cases they had under treatment. Despite the legal requirements the report was incomplete. There were reported 5835 cases, of which 4159 were gonorrhea, 778 were soft chancre, and 898 syphilis; that is to say, 71.2 per cent. gonorrhea, 13.3 per cent. soft chancre, and 15.4 per cent. syphilis. The student body, unfortunately, makes a special group of the population, distinct from the rest by the frequent occurrence of the disease. Out of 2140 students, 216 in the course of the year suffered from venereal disease. Of these, 147 had gonorrhea, 26 soft chancer, and 43 syphilis.

We owe it to Noeggerath for having shown how prevalent is gonorrhea in the female sex and how serious its consequences may be. As has been said, it is here that statistics are most imperfect. By reason of the number of suspicious cases that occur in large public polyclinics it is impossible for the busy gynecologist to make a serious investigation in every case in order to obtain proof that gonococci are present. If the clinical symptoms alone are considered the number will, in my opinion, always be too high. This source of error will, however, be more than compensated for by the number of cases which are passed over either because their symptoms are too slight to call for medical attention, or because the manifestations of the disease are not sufficiently clear to suggest a careful examination. Saenger, out of his entire gynecological material, considers that 12 per cent. suffer from gonorrhea. Robert Asch found 14 per cent. Zweifel, in his private practise, found 10 per cent. These figures, it seems to me, are calculated to give a rather correct idea of the significance of gonorrhea as a disease of the female sex. Until the last decade or two, we were accustomed to consider the disease as not having any very serious importance in spite of our knowledge of its wide prevalence. It was looked upon rather as an annoying disorder which, because of certain painful complications, not infrequently became a distressing affection. It is only the work of the last two decades which has made the significance of gonorrheal infection clear. A large number of serious affections, some of which are followed by irremediable sequelæ, the cause of which was heretofore entirely unknown, are now recognized to be gonorrheal in origin. This is especially true of the disease in women. We now know for the first time how serious the danger is to the general population from the terrible prevalence of this infectious disease.

The following circumstances make gonorrhea a serious and often dangerous disease:

1. The affection does not remain limited to the primary focus of infection in the mucous membrane of the anterior urethra of the man, or the urethra or cervix of the woman, but progressively invades other parts. (*a*) Its first advance is to higher portions of the urinary tract; the neck of the bladder, the bladder itself, the ureter, and the pelvis of the kidney. The acute affections of these organs lead frequently to painful and often to febrile conditions which keep the patient in bed. Chronic conditions often develop, whose frequent and ever-recurring attacks of pain with frequent exacerbation lay the foundation for serious nervous disturbances of many kinds. (*b*) The next point of attack is the genital tract, and the disease advances along this. An acute purulent or chronic inflammation of the prostate, and then seminal vesiculitis or inflammation of the vas deferens and of the epididymus occurs. The affection of the prostate usually causes no immediate disturbance of the genital function. The chronic form, however, affects the potentia coeundi injuriously, causing inefficient erection, precocious ejaculation, and

irritable weakness of the genital functions generally, by setting up local nervous disturbances and neurasthenia. It is possible also that alteration in the prostatic secretion may interfere with the motility and consequently with the potency of the spermatozoa.

If the gonorrhea attacks the prostate direct treatment becomes impossible. This localization of the disease takes on a very special interest in its relation to that important question whether absolutely incurable cases do not exist; that is to say, cases which remain persistently infectious despite all treatment. This question, to my mind, unfortunately must be answered in the affirmative. Affections of the vas deferens and of the epididymus are of more importance, as it is by means of these that the largest number of cases of impotence are occasioned. Notwithstanding perfectly normal functioning of the testicle, the inflammation so closes up the epididymus, the vas deferens, and the seminal vesicles, that in a large number of cases it produces an absolute mechanical hindrance to the progress from the testicle to the urethra. In spite of perfect potentia coeundi, a man with double gonorrheal affection of the seminal conducting apparatus is frequently sterile. Gonorrheal affections of the epididymus are therefore not only extremely annoying affections, lasting for a week or two, but may be most serious complications which absolutely prevent procreation.

In the woman gonorrhea advances from the mucous membrane of the cervical canal to the internal genitalia, and the whole internal apparatus, the uterus, the tubes and ovaries, and the peritoneum may become infected. The various affections that are thus caused may be briefly mentioned. The primary infection of the cervical canal usually gives no subjective symptoms. For this reason innumerable women are absolutely ignorant of the fact that they have been infected or that they carry with them a disease that may be communicated to others. The swelling and catarrhal inflammation of the cervical mucosa may present a mechanical hindrance to the entrance of spermatozoa into the uterus. Very subjective symptoms either in the form of persistent pain or in the form of recurring attacks of pain especially at the menstrual period may be caused by endometritis. Apart from the serious dysmenorrhea itself, this affection is a frequent cause of sterility. The implantation of the impregnated ovum is hindered, or after its implantation, abortion occurs. Should pregnancy continue to term, the endometritis is frequently a cause of dangerous bleeding. Puerperal infection often results and this in turn may produce persistent incapacity for all future conception, and may lead to what is called one-child sterility.

Should the infection reach the tubes an acute febrile affection with severe attacks of pain, combined with tumor-like swellings of the tube (salpingitis), occurs, which even in the most favorable cases keeps the patient in bed for weeks, and requires most careful treatment. Even after this the condition usually is not entirely cured, but leads to chronic persistent ill health with frequent acute exacerbations. These recurring acute attacks often become dangerous to life, so that operative interference and removal of the collections of pus by laparotomy becomes inevitable. Fatal peritonitis may result from gonorrheal salpingitis. When both tubes are affected there is every prospect of lasting sterility.

The most frequent and severe disturbances of health—they are also the most dangerous—arise from the extension of the inflammatory process from the uterine mucosa directly or through the tubes to the peritoneal surfaces of the ovaries. The peritoneal affections which result from this extension cause disturbances of menstruation, colic-like attacks of pain, and neurasthenic complications and sequelæ. Such occupy the attention of the gynecologist and every year bring to our watering-places an army of women suffering from pelvic disease. This constitutes the most serious result of gonorrhea in the female, and often leads to complete invalidism for years. These peritoneal affections, by causing mechanical disturbances in the position of the uterus and inflammatory adhesions of the uterus and its adnexa, may also be a fruitful cause of sterility.

The dangers we have pictured to which every woman infected with gonorrhea is liable are very much increased during the puerperium. At this time the extension of the gonorrheal process to the internal sexual organs is extremely easy. All of the complications of ascending gonorrhea that have been mentioned, especially "single-child sterility," are greatly favored.

The saddest feature in this whole picture of gonorrhea, the details of which we cannot stop to enumerate, is that once the infection has gained a foothold in the uterine mucosa, there is scarcely any medical treatment that is of any service. In spite of every effort that has been made to destroy the gonococci, most gynecologists have reached the conclusion that the surest and best hope for ultimate cure is to spare the woman as much as possible and provide her, as far as practicable, with absolute rest. Very naturally, however, it is just those women who most need their health and capacity for work—the women of the poorer classes—who are least able to follow the prescriptions of absolute rest in bed for weeks, perhaps months. As a consequence there develops among this class of patients those severe and often dangerous conditions which necessitate operations. Such operations are indicated not only from a purely medical standpoint but also from a humane and social point of view, since the operative removal of the diseased tissues will most surely and soonest lead to health and the ability to resume work. A double operation causes sterility, but this is not a consequence that is usually considered of any very serious importance.

2. The affection does not limit itself to the superficial mucous membrane, although this is

not the most often affected, but gives rise to other affections. (*a*) These affections result either from toxic products of the gonococcus producing effects at a distance from the original focus of infection, or from localized abscesses in the neighborhood of the urethra, which lead to the formation of cicatricial tissue in the neighborhood of the urethra. These peri-urethral abscesses in the male sometimes cause fistulæ or scars in the corpora cavernosa, and these interfere with erectile power, and hence disturb the potentia coeundi. Strictures of the urethra result, which not only disturb the evacuation of urine, but also interfere with the normal seminal evacuation. Frequently, in later years, these strictures cause severe bladder and kidney trouble, and their treatment requires time and expense. Only occasionally is operative interference of any use.

In the woman, suppuration of the Bartholinian glands occurs. This requires treatment with absolute rest in bed for several weeks, and not infrequently gives rise to annoying fistulæ, some of which may establish a connection with the rectum and later produce intractable rectal ulcers and strictures. (*b*) The gonococci may force their way into the connective tissue of the mucous membrane, and then find entrance into the lymph or blood circulatory systems, and so give rise to metastases all over the body. Such an invasion of gonococci gives rise: (1) To arthritic affections, most of which demand treatment for weeks or even months. Such often are subject to distressing repeated relapses during later life, occasioning serious disturbance of function. (2) They may cause affections of the cutaneous connective tissue of the glands or purulent affections of the tendon sheaths. (3) They may cause serious affections of the heart and the blood-vessels, endocarditis, pericarditis, phlebitis, etc. (4) They may even give rise to systemic intoxication through toxins produced by the gonococci, and so occasion cachexia and affections of the central and peripheral nervous system, or various erythematous, hemorrhagic, or hyperkeratitic forms of skin disease; or they may cause serious disturbances of the organs of the special senses; conjunctivitis, iritis, optic neuritis, etc. (5) Gonorrhea of the genital organs acquired by sexual intercourse is often the source of other localizations of the disease, which, for their part, cause severe systemic disturbances.

(*a*) *Gonorrhea of the Conjunctiva.*—Besides the comparatively rare infections of this kind in adults it is well-known how frequent is blenorrhea neonatorum. This affection is caused in the majority of cases by the infection of the child during labor with the gonococci, which are present in the mother's genital canal. In a goodly proportion of the cases it leads to loss of the infected eye, and when the affection occurs on both sides, is a frequent cause of total blindness.

(*b*) *Gonorrhea of the Mucous Membrane and the Rectum.*—This affection occurs mostly in women as a consequence of the infection of the rectal mucosa by secretions flowing down from the genitalia. Ulcerative lesions and purulent conditions of the connective tissue around the rectum are sequels which eventually cause stricture, and thus induce permanent invalidism. Sometimes in men and boys, as well as in women, direct infection of the rectum takes place through anal coitus.

(*c*) *Gonorrhea of the Oral Mucous Membrane.*—This occurs very seldom and has not much significance.

Very naturally no exact statistics exist as to the frequency of these complications, sequelæ, and metastases, nor of their proportion to the number of infections. There are many reasons for this: (1) In many cases the true character of the arthritic and heart affections is not recognized; they are not considered the sequelæ of a preceding gonorrhea; (2) these severer forms of gonorrheal affections come much more frequently under medical treatment, and especially enter oftener into the statistics of hospitals, clinics, and so forth, than does uncomplicated gonorrhea. All of our reports in this matter are therefore either too low or too high. One thing alone is certain, and that is that thousands and even tens of thousands of people, men and women, are to be found in every civilized country whose health has been seriously undermined, whose capacity for work greatly lessened, and who owe their state of chronic invalidism to gonorrhea.

I limit myself here to a few statistics which seem to give an approximate idea of the frequency and significance of gonorrheal complications. The statistics of the Breslau physicians gave, out of 3699 cases of gonorrhea, 1002 complications, as follows: Cystitis, 356; epididymitis, 269; prostatitis, 85; strictures, 69; Bartholinitis, 67; vulvitis and vaginitis, 78; affections of the adnexa, 49, and arthritis, 29. The following tables bring together a number of individual statistics as to gonorrhea in the male. The first contains 28,787 cases, in which there were 27.1 per cent. of epididymitis and 17.8 per cent. of all other complications. A second table contains 256,261 cases of gonorrhea with 14.8 per. cent. of epididymitis. Both together give 16.11 per cent. of epididymitis in 285,048 cases of gonorrhea. A glance at the totals, as well as the details of these cases, shows how little such percentages are to be depended on. While the average occurrence of epididymitis is 16.1 per cent. the number of cases of this complication in individual statistics varies between 3.5 per cent. and 39.3 per cent. It is clear that these variations depend upon the differences of the material that came under the observation of the different reporters. In clinics and hospitals the admissions of cases of epididymitis will very naturally be disproportionately high in comparison with the statistics of polyclinics and out-patient dispensaries, while the last will be very much higher than the statistics gathered from private practise. The best average, it seems to me, can be gathered from the reports of the Breslau physi-

cians. Since we have in these all the sources of error combined to more or less neutralize one another. The Breslau statistics give 8.89 per cent. of epididymitis.

Unfortunately there is one factor which has not been sufficiently reckoned with in making up the statistics, namely, the method of treating uncomplicated gonorrhea. It is surely beyond doubt that frequency of complications depends on the method of treatment and can, therefore, be very much lessened if a proper method of treating gonorrhea is instituted as soon as it makes its appearance. With reference to the complications of gonorrhea in the female we have insisted on the importance of these before. It is rather shocking, then, to learn that Saenger finds that not less than 50 per cent. of the women who come to him with gonorrhea develop severe complications, while Schultz and others report 33.3 per cent. Herzfeld found 18 per cent. of gonorrheal adnexa affections in the whole gynecological material of Schauta's polyclinic; Lier-Ascher reports 31 cases of urethritis and endometritis and 68 cases of tubal affections in 95 women suffering from gonorrhea. In my opinion these figures are too high, since we have not included in them the simple gonorrheal infections without complications. I am of the opinion that Bumm is more nearly right when he places the proportion at 14 per cent. of uterine complications and 3.6 per cent. of tubal complications in gonorrhea.

A special mention and word of warning is due to gonorrheal arthritis, because of its frequency, its slow-running course, and tendency to relapses, with ankylosis and disability. At times even suppuration of the joints results and constitutes it a very serious affection for the working classes. Gerhardt found in 928 cases of arthritis that 7.43 per cent. were gonorrheal in origin. In 4423 cases of gonorrhea Gricolle found 68 cases of arthritis (1 in 6.5). Koenig found in two years in his surgical clinic at Berlin no less than 56 cases of gonorrheal arthritis. Of these 56 cases, 38 were in women, which is a striking bit of evidence of the extreme frequency of gonorrhea in the female, since it often remains entirely unnoticed. Rindfleisch, in Bergmann's clinic in Berlin, found in one year 19 cases of gonorrheal arthritis.

(To be continued.)

EXPERIMENTAL TESTS AT VERA CRUZ, MEXICO, OF THE DOTY-FITZPATRICK SERUM FOR THE PREVENTION AND CURE OF YELLOW FEVER.

BY A. MATIENZO, M.D.,
OF TAMPICO, MEXICO;
CORRESPONDING FELLOW OF THE MEDICAL ACADEMY OF MEXICO AND OF THE ACADEMY OF SCIENCES OF MADRID, SPAIN; CHIEF SURGEON OF THE CIVIL HOSPITAL, AND HEALTH OFFICER OF THE PORT OF TAMPICO.[1]

THROUGH the kindness of Dr. Edward Liceaga, President of the Board of Health of Mexico, I was commissioned to assist Dr. Barnard E. Baker, deputy of Dr. Alva H. Doty, Health Officer of the Port of New York, in the bacteriological experiments and investigations made at Vera Cruz with the serum obtained from the Health Department of the City of New York.

Before speaking of the results it seems advisable to me to explain the experiments and the technic employed in obtaining the serum that was expected to be curative and preventive of yellow fever.

According to Dr. Charles B. Fitzpatrick, director of the bacteriological laboratories of the New York Health Department,[1] the advantages of the serum treatment in yellow fever were very manifest, and it was, therefore, with the view of obtaining a serum for the treatment of this disease that a series of experiments were begun in the laboratories of the department by Dr. Alva H. Doty.

The work, preliminary to the preparation of the serum, was to obtain pure cultures of the microorganism that bears an etiological relation to the disease. In March, 1897, he isolated a microorganism from the blood of three cases of yellow fever which he described as bacillus coli icteroides, regarding it as a special and virulent form of the bacterium coli commune. Comparisons made afterward with the bacillus icteroides sent by Sanarelli led him to conclude that these two organisms were practically the same, and their pathogenic powers convinced him that they bore an etiological relation to yellow fever, notwithstanding their intimate connections with the bacillus coli commune. The methods employed in the immunization of the animals with the bacillus icteroides were essentially the same as those the author used to obtain the diphtheria antitoxin serum, and the cultures used to produce the toxins with which animals were inoculated were the cultures of the bacillus icteroides which Dr. Sanarelli sent to the health officer's department. Two horses were selected for immunization in order to obtain from their blood the preventive and curative serum. The injection fluids were composed of the living cultures or the filtered cultures. The cultures were allowed to grow at 37° C. (98.6° F.) for about twenty-five days and then filtered; the filtrate contained a toxin of varying strength.

The intrajugular injection of two or three hundred cubic centimeters of the toxin generally caused a temperature reaction of two degrees C. in a horse that had previously undergone the process of immunization for fifteen months. Subcutaneous injections of the living cultures were not well tolerated and caused extensive necrosis of the tissues. The toxin injections were better tolerated but were not so satisfactory as the intravenous injections of the filtered toxins. The necrosis of the subcutaneous tissues resulting from extravasations of intravenous and subcutaneous injections was so extensive that it resulted in the death of one of the horses. The

[1] Report to the Board of Health, Mexico.

[1] "Notes on the Treatment of Yellow Fever with the Blood-serum of the Bacillus Icteroides," Medical Record, July 1, 1899.

virulence of the culture used has varied. The original culture sent to the laboratory by Dr. Sanarelli, when injected in doses of ½ c.c. or more, intraperitoneally, caused the death of a guinea-pig weighing 300 grams in about seven days. On increasing the virulence of the culture so that the subcutaneous injection of ½ c.c. caused death, the results were as follows: (1) Guinea-pig, weight 235 grams, inoculated subcutaneously with 1 c.c., died in six days. (2) Guinea-pig, weight 235 grams, inoculated subcutaneously with 2 c.c., died in three and one-half days. (3) Guinea-pig, weight 260 grams, inoculated subcutaneously with 3 c.c., died in two and one-half days.

"It may readily be seen from the above," says the author, "that the culture does not cause in guinea-pigs a disease with a definite cycle or an infection which has a definite period of incubation and development. The intensity of the infection depends upon the dose. With a similar dose death takes place in some cases as late as nineteen days after the injection. The character of reaction in horses has been that of a direct rise of temperature within twenty-four hours and a fall to about normal within the next twenty-four hours. Subcutaneous injections and extravasations from the veins caused a more gradual descent, or a fall followed by a rise." The horse which lived was first injected in January, 1898, and was methodically injected, at the proper intervals, until June 15, 1899. The blood-serum of this horse first began to show therapeutic properties on October 18, 1898. The serum of that date was effective to the extent that when the guinea-pigs were inoculated with a fatal dose of culture of the bacillus icteroides, two of which had twelve hours previously received an injection of the blood-serum, the two remained alive two and three days longer than the remaining guinea-pig which had not received the serum treatment.

1. Guinea-pig, weight 245 grams, received a subcutaneous injection of 2 c.c. of serum November 6, 1898, and twelve hours later was inoculated with a fatal dose of the culture. Died November 14, 1898.

2. Guinea-pig, weight 255 grams, received a subcutaneous injection of 1 c.c. serum November 6, 1898, and twelve hours later was inoculated with a fatal dose of the culture. Died November 15, 1898.

3. Guinea-pig, weight 255 grams, received no injection of the serum and was inoculated November 6, 1898, at 9 P. M. as above. Died November 12, 1898.

The succeeding experiments gave varying results. A much stronger serum was obtained, however, on May 2, 1899. Fourteen cubic centimeters of this, when injected into a guinea-pig, which was at the same time injected with a fatal dose of the culture, cured the animal so injected. If it had not received the serum injection, it would surely have died, as was proved by the death of another and larger guinea-pig that was injected with a fatal dose of the culture at the same time, and under exactly the same conditions as the one treated and cured by the serum. The one which died eighteen days after the inoculation, although a larger and much stronger animal than that which was cured, was treated in every way the same as the cured one with the single difference that the one that died did not receive any injection of the serum. A smaller dose of the serum (10 c.c.) succeeded in preventing the infection in a guinea-pig injected with a fatal dose of the bacillus icteroides, twenty-four hours later. The control guinea-pig which was inoculated at the same time and which had received no serum, died in nine days. Both the guinea-pig that was cured and the one in which the infection was prevented have remained alive and well over a month since the death of the animals which received no treatment with the serum.

Examples Showing the Preventative and Curative Action of Serum.

1. Guinea-pig, weight 350 grams, received 14 c.c. serum at 4 P. M., May 3, 1899; one hour afterward it received 3 c.c. of culture. It has remained alive and well. A control guinea-pig, weight 390 grams, received no serum but was inoculated with 3 c.c. of the same culture as the above. It died May 21, 1899.

2. Guinea-pig, weight 330 grams, received 10 c.c. of serum at 4 P. M., May 3, 1899, and twenty-four hours afterward was inoculated with 3 c.c. of the culture. It has remained alive and well. A control guinea-pig, weight 330 grams, received no serum as above, but was inoculated with 3 c.c of the same culture. It died May 12, 1899.

Serum obtained May 31st has also shown about the same strength as the serum obtained on May 2d. Ten cubic centimeters of the serum were sufficient to prevent infection and death in a guinea-pig 300 grams in weight, although a much heavier guinea-pig, 372 grams in weight, inoculated at the same time and which received no serum treatment died on June 16th.

The serum, so prepared, concludes the author, compared by a series of experiments with the serum obtained from the laboratory of Dr. Sanarelli, in Montevideo, Uraguay, has given more uniform results than the South-American serum.

Injections Made with the Curative Serum at Vera Cruz.

Case I.—Manuel Rodrigues, thirty-five years of age, native of Hidalgo, has been in Vera Cruz two months, entered the Military Hospital July 10, 1899, at 4 P. M. Disease began on July 9th at 11 A. M. with chills, headache, and pains in the back. He did not feel pain in the stomach and did not vomit. At the present time, July 11th, the conditions are as follows: Sandy tongue, slightly reddish at the tip and edges, eyes bloodshot, gums reddish and somewhat swollen, urine albuminous. His temperature on the day of entrance, 39.3° C. (102.6° F.); to-day at 8

A. M., 39.5° C. (103.1° F.); pulse 92, regular and strong, no vomiting. At 9:40 A. M. he received an intravenous injection of 15 c.c. serum; temperature immediately after injections 39.4° C.; pulse 80; the patient did not suffer pain. At 10:40 A. M. temperature 39.4° C. (103° F.); pulse 80; 2:30 P. M., temperature 40° C. (104° F.), pulse 76; 6 P. M., temperature 39.5° C. (103.1° F.), pulse 76.

July 12th: Headache, eyes still bloodshot and slightly jaundiced; albumin in urine in larger quantity than yesterday, above 25 per cent. At 8:30 A. M. he received an intravenous injection of 20 c.c. serum, and another subcutaneous injection of 10 c.c. Temperature and pulse were as follows: 7:30 A. M., temperature 39.3° C. (102.6° F.), pulse 64; 7:20 P. M., temperature 39.6° C. 103.3° F.), pulse 72. The same conditions prevailed during the day with the exception of the febrile reaction, caused by the injections. Pulse very weak; nausea, without vomiting.

July 13th: Same condition, slight headache, jaundice of the eyes, albumin in the urine in the same proportions as day before; no delirium. Temperature and pulse as follows: At 8 A. M., temperature 39° C. (102.2° F.), pulse 64; 5:30 P. M., temperature 39.3° (102.6° F.), pulse 72; an adynamic condition; pulse very weak; no vomiting; urine albuminous; he was not given an injection.

July 14th: Pulse very weak; adynamic condition more marked, gums more reddish and swollen; no vomiting, nor pain in the stomach; a great deal of albumin in the urine. Temperature and pulse: At 8 A. M., temperature 38.6° C. (101.4° F.), pulse 72; 12 M., temperature 38.5° C. (101.2° F.), pulse 76. He received four subcutaneous injections of 15 c.c each at 12, 3, 6 and 9 P. M.; 6 P. M., temperature 38.8° C. (101.8° F.), pulse 84

July 15th: He had some vomiting of mucus; prostrated condition; tongue red and dry; eyes jaundiced; albumin in the urine, about 15 per cent.; pain in the regions injected. Temperature and pulse: At 6 A. M., temperature 37.7° C. (99.9° F.), pulse 80; 6 P. M., temperature 38.4° C. (101° F.), pulse 87. He received three subcutaneous injections, each of 15 c.c. of serum, at 1:30, 4:30, and 7:30 P. M.

July 16th: He continued during the preceding evening in the same condition of depression, and during the night had hiccough, and involuntary urination and defecation. At 8 A. M. very grave condition; weak pulse; dry tongue; hemorrhage from the left ear; gums much swollen but not bleeding; jaundiced condition pronounced; hiccough and dorsal decubitus; flies on the face and hands of the patient. Temperature and pulse: At 8 A. M., temperature 38° C. (100.4° F.), pulse 72; 12 M., 37.4° C. (99.5 F.), pulse 80; 6 P. M., temperature 38° C. (100.4° F.), pulse 80. No injection of serum as the case appeared very desperate.

July 17th: Same conditions; hiccough ceased; albumin in urine, 10 per cent. Temperature and pulse: At 7 A. M., temperature 37.8° C. (100° F.), pulse 72; 4 P. M., temperature 38° C., pulse 70; 6 P. M., temperature 37.5° C. (99.5° F.), pulse 78.

July 18th: Hiccough returned, although the general condition is not so bad; moist tongue; albumin 15 per cent.; icterus excessive in the eyes; no vomiting. July 19th: Normal temperature; out of danger and on the road to recovery.

Case II.—Rafael Veloz, thirty-six years of age, nurse in the Military Hospital of Vera Cruz. He arrived eleven days ago in Vera Cruz from the City of Mexico. He became ill on July 10th at 4 P. M. Had chills and fever; headache and pain in the back; pain in the stomach and vomiting. At 9 A. M. on the 11th his condition was as follows: Face and eyes bloodshot; tongue coated, red at the tip and on the edges; copious vomiting of mucus; tenderness in the stomach; headache; pain in the back; gums injected; no albumin in the urine. At 9 A. M. he received an intravenous injection of 20 c.c of serum obtained on May 31, 1899, and a subcutaneous injection of 10 c.c. of the same serum. Temperature and pulse: At 8 A. M., temperature 39.8° C. (103.6° F.), pulse 108; injection; 2:30 P. M., temperature 40.4° C. (104.7° F.), pulse 108; 6 P. M., temperature, 39.8° C. (103.6° F.), pulse 110; 9 P. M., temperature 39.8° C. (103.6° F.), pulse 108. In the evening the same conditions prevailed; frequent vomiting; albumin in the urine about 25 per cent.

July 12th: Same condition. Vomiting and tenderness in the stomach; headache; pain in the back; slight icterus in the eyes; very rough tongue; gums very red; pain in the pectoral regions, where he received the subcutaneous injection. At 7:45 A. M. he received an intravenous injection of 20 c.c. of serum and a subcutaneous injection of 15 c.c. of the same serum. Temperature and pulse: at 7:30 P. M., temperature 39° C. (102.4° F.), pulse 88; 11 A. M., temperature 39° C. (102.2° F.), pulse 86; 7:20 P. M., 38° C. (101.8° F.), pulse 80; in the evening no change; very albuminous urine.

July 13th: Great tenderness in the gastro-hepatic region; albumin and biliary pigment in the urine; eyes jaundiced. No injection of serum was given. Temperature and pulse: At 8 A. M., temperature 38.4° C. (101.1° F.), pulse 88; 12 M., temperature 39.4° (102.9°F.), pulse 88; 5:30 P. M., temperature 38.3° C. (101.1° F.), pulse, 88; in the evening same condition.

July 14th: No range in his condition; albumin in the urine about 20 per cent. He received three subcutaneous injections, each of 15 c.c. of serum, at 12:30, 4:30, and 8:30 P. M. Temperature and pulse: At 6 A. M., temperature 39.3° C. (102.7° F.), pulse 90; 6 P. M., temperature 39.4° C., pulse 92. In the evening vomited black matter.

July 15th: No more vomiting. Great pain in the region where he received the subcutaneous injections; icterus more pronounced; bilious and albuminous urine. He received three subcutaneous injections, each of 15 c.c. of serum, at

1:30, 4:30, and 7:30 P. M. Temperature and pulse: At 6 A. M., temperature 38.7° C. (101.6° F.), pulse 100; 12 M., temperature 38.6° C. (101.5° F.), pulse 90; 4 P. M., 39.4° C. (102.9° F.), pulse 98.

July 16th: Same condition; bleeding from the gums; restlessness; albumin in urine about 15 per cent. Temperature and pulse: At 6 A. M., temperature 38.4° C. (101.1° F.), pulse 90; 4 P. M., temperature 38.1° C. (100.6° F.), pulse 88.

July 17th: Condition very grave; gums bleeding; no more vomiting; pain in the stomach and in the places injected. On account of the grave condition of the patient he received no further injections.

July 18th: Condition extremely grave; restless; complaining; blood in the mouth; scanty and albuminous urine. Patient died at 12:15 P. M.

Autopsy.—At 1 P. M. Body very yellow (icterus post-mortem). Hypostatic spots in the neck and in the back; cellular tissue very yellow; blood in the mouth; liver slightly enlarged and yellow, resembling a nutmeg liver. On sectioning the tissue it did not bleed and appeared in an advanced stage of fatty degeneration; spleen normal in shape, blackish, in a state of very intense congestion; tissue much altered, tears away easily; lungs normal; mucous membrane of stomach congested and hemorrhagic in spots; the stomach contained the characteristic black blood; kidneys congested, on sectioning, hyperemic, with yellow spots of fatty degeneration. Intestines in same condition as the stomach. Bladder contained a little urine.

Case III.—Juan Vega, Eighth Infantry, living in the Ulna Prison. He arrived at Very Cruz three months ago from Chilpanango (Guenro State). He was taken ill on the 11th of July, in the afternoon, with chills, headache, and pain in the back; no vomiting.

July 14th: Same conditions and some pain in the stomach. Since the 13th albumin had been found in the urine. Temperature and pulse: July 11th, in the evening, 38° C. (100.4° F.); July 12th, in the morning, 37.5° C. (99.5° F.); P. M., 40° C. (104° F.); July 13th, 11 A. M., 39.5° C. (103.1° F.), pulse 96; 12:30 P. M., 39.1° C. (102.4° F.), pulse 96; 7:30 P. M., 39.3° C. (102.6° F.), pulse 96. At 10:30 A. M. he received a subcutaneous injection of 30 c.c. of serum, and another injection every four hours of the same quantity; that is to say, 90 c.c. in the daytime.

July 14th: Same condition. Eyes injected and slightly jaundiced; tongue coated and red at tip; swollen gums, and pain in the stomach; very frequent mucus vomiting; albumin in the urine, about 15 per cent.; at 6 A. M., bloody stools. He received four subcutaneous injections at 10:30 A. M., 30 c.c. of serum; at 1:30 P. M., 20 c.c. of serum; at 4:30, 20 c.c. of serum; and at 7:30, 20 c.c of serum. Temperature and pulse: 6 A. M., 39.1° C. (102.4 F.), pulse 96; 10:30 A. M., 38.5° C. (101.3 F.), pulse 104; 1:30 P. M. 39° C. (102.2° F.), pulse 108; 7:30 P. M., 38.7° C. (101.6 F.), pulse 106. Condition very grave during night-time. Delirium and hiccough.

July 15th: Convulsions; eyes jaundiced; pain in the stomach; swollen gums; albumin in the urine, about 60 per cent. Shortly before death there was the characteristic black vomit. Temperature and pulse: 6 A. M., 37.5° C. (99.5° F.), pulse 108; 3 P. M., 37.1 C. (98.8° F.), pulse 112.

Autopsy.—The body was rigid and very yellow; black blood in the mouth; hemorrhagic focus in the place of the first injection; liver of normal size and of color of dead leaves. A section of the liver showed fatty degeneration; the spleen was normal in size, softened, and dark in color; the kidneys were enlarged, hyperemic, and in some points there was fatty degeneration of the renal epithelium; no urine in the bladder; lungs show congestion at the base; the heart was found to be very pale, but apparently of normal size and condition; the stomach was very much congested, showed some hemorrhagic spots in the mucous membrane; the intestines presented similar changes.

Case IV.—Amelio Canales, twenty-five years of age, Eighth Infantry at Ulna. He arrived at Vera Cruz eight months ago from Puebla. He was taken ill on the 12th of July in the afternoon, with chills, pain in the back and headache, pain in the stomach, and vomiting of food and drinks. Same condition on July 13th; tongue coated and red at the tip; gums swollen and epigastric tenderness. Temperature July 12th, in the morning, 40° C. (104° F.); in the evening, 39° C. (102.2° F.); temperature of July 13th, in the morning, 38° C. (100.4 F.); in the evening, 39° C. (102.2° F.); July 14th, same condition; headache; pain in the back; albumin in the urine; conjunctivæ much bloodshot. He received four subcutaneous injections each of 30 c.c. of serum, at 11:30, 3:30, 7:30, and 11:30 P. M. Temperature and pulse: 6 A. M., 39.5° C. (103.1° F.), pulse 80; 11:30, 39.5° C. (103.1° F.), pulse 84; 7:30 P. M., 39.1° C. (102.2° F.), pulse 92; 11:30 P. M., 37.5° C. (99.5° F.), pulse 86.

July 15th: Same conditions; swollen gums; no icterus; some pain in the stomach; bilious stools; very little albumin in the urine, about 5 per cent. He received four subcutaneous injections of 30 c.c. each of serum, at 9:30, 1:30, 5:30, and 9:30 P. M. Temperature and pulse: 6 A. M., 38.9° C. (102° F.), pulse 98; 9:30 A. M., 38.5° C. (101.3° F.), pulse 86; 1:30 P. M., 39.3° C. (102.7° F.), pulse 102; 5:30 P. M., 38.3° C. (101.1° F), pulse 92; 9:30 P. M., 38° C. (100.4° F.), pulse 90.

July 16th: Eyes slightly jaundiced; gums somewhat swollen; has no vomiting nor headache; very little albumin in the urine. Temperature and pulse: 6 A. M., 38° C. (100.4° F.), pulse 94; 10 A. M., 38.8° C. (101.8 F.), pulse 92; 6 P. M., 39° C. (102.2° F.), pulse 88. July

17th: Eyes jaundiced; recovery began in the morning. Temperature and pulse: 37.5° C. (99.5° F.), and pulse 84. July 18th: Temperature, A. M., 37° C. (98.6° F.), pulse 70; P. M., 36.5 C. (97.7° F.), pulse 66.

July 19th: Temperature, A. M., 36.0° C. (96° F.), pulse 60; gums bleeding a little; eyes still bloodshot and more jaundiced; very little albumin in the urine; convalescence.

Case V.—Pedro Hernandez, twenty-three years of age, Twenty-third Infantry. He arrived at Vera Cruz two months ago from Guanajuato; entered the Military Hospital July 19th. He became ill July 18th at 1 o'clock A. M., with slight chills, fever, headache, and pain in the back; without vomiting or pain in the stomach. In the evening the eyes were bloodshot, temperature 39° C. (102° F.), pulse 88. No albumin in the urine; apparently a very slight attack of the disease.

July 19th: At 8 A. M. the temperature was 38.3° C., pulse 64; same conditions; no vomiting; small amount of albumin in the urine; coated tongue; gums injected; no pain in the stomach. He received of serum No. 1, without carbolic acid, obtained on June 30, 1899, four subcutaneous injections as follows: 8 A. M., 30 c.c.; 12 M., 30 c.c.; 4 P. M., 30 c.c.; 8 P. M., 45 c.c.: total amount of serum injected, 135 c.c. in twenty-four hours. Temperature and pulse: 8 A. M., 38° C. (100.4° F.), pulse 64 (first injection); 12 M., 40.3° C. (104.5° F.), pulse 80 (second injection); 4 P. M., same (third injection); 8 P. M., 40.6° C. (105.1° F.), pulse 100 (fourth injection). In the evening the same condition prevailed, save for the reaction caused by the injections of serum.

July 20th: Same condition; no vomiting or pain in the stomach; about 1 per cent. of albumin in the urine; great pain at site of injection. Temperature, pulse, and injections: 8 A. M., 39.4° C. (102.9° F.), pulse 88, injection of 30 c.c. of serum; 12 M., 39.7° C. (103.5° F.), pulse 88, injection of 30 c.c. serum; 4 P. M., 39.7° C. (103.5° F.), pulse 88, injection of 40 c.c. serum; condition same as yesterday.

July 21st: Defervescence and beginning of the second period of the disease. Temperature and pulse: 8 A. M., 38.3° C. (100.9° F.), pulse 80; 12 M., 39.5° C. (103.1° F.), pulse 88; 4 P. M., 38.4° C. (101° F.), pulse 80.

July 22d: Same good condition. Gums reddish; little albumin in the urine. Temperature, 8 A. M., 37.8° C. (100° F.), pulse 80; at 4 P. M., 37.5° C. (99.5° F.), pulse 80; recovered.

Case VI.—Harlindo Guevara, twenty-four years of age. He arrived at Vera Cruz six months ago from Puebla, entered the Military Hospital July 25th, in the afternoon. He began to be sick July 24th, with chills, fever, headache, vomiting, and pain in the back and legs. He remained the same during the 25th, and on the 26th presented the following conditions: Eyes injected; gums reddish; tongue coated red at the tip and borders; epistaxis and nausea, and tenderness in the epigastrium; albumin in the urine. At 10 A. M. he received two intravenous injections of 21 c.c. and 25 c.c. of serum No. 1, obtained July 3, 1899; total serum injected, 46 c.c. Temperature and pulse: 10 A. M., 39.8° C. (103.7° F.), pulse 108, injection; 12 M., 40.2° C. (104.4° F.), pulse 110; 4 P.M., 40° C. (104° F.), Pulse 120. Intense reaction caused by the serum.

July 27th: Mucus vomiting; eyes injected; swollen gums; epigastric tenderness; headache and great pain in the back; 40 to 50 per cent. albumin in the urine. 8 A. M. subcutaneous injections of 25 c.c. of the same serum. In the evening the same conditions existed with mild conjunctival jaundice. Temperature and pulse: 8 A. M., 39.7° C. (103.5° F.), pulse 88, injection; 10 P. M., 40° C. (104° F.), pulse 116. In the evening reaction caused by the serum less intense than the one observed the day previous with the intravenous injection.

July 28th: Slight remission of temperature, pulse notwithstanding is frequent, indicating internal hemorrhage. In the morning he had a stool with slight traces of black blood; jaundice of eyes marked; vomiting less frequent; epigastric pain less intense; large quantities of albumin in the urine At 8 A. M. he received one subcutaneous injection of 25 c.c of serum. Temperature and pulse: 8 A. M., 38.3° C. (100.9° F.), pulse 104, injection; 4 P. M., 39° C. (102° F.), pulse 120. In the evening, black vomit; jaundice marked, and bad general condition.

July 29th: Same condition; extensive jaundice in the face; suppression of urine; gums swollen; pain in the stomach; pulse very weak and rapid; temperature, 8 A. M., 38.4° C. (101.1° F.), pulse 102; 4 P. M., 37.6° C. (99.7° F.), pulse 112. In the evening, condition of collapse; extremities cold. He had one darkly-stained stool, and died at 7 A. M. of the 30th, without convulsions.

Autopsy.—One hour after death, rigor mortis well developed, extensive jaundice, black patches in the neck and back, black blood in the mouth. The liver was larger than normal, yellow, and on section showed fatty degeneration. The spleen seemed enlarged, softened, and dark red. The kidneys were enlarged with areas of pyemia and fatty degeneration; the heart normal; yellow serum in pericardium, and congestion at base of lungs; stomach contained quantity of black blood with coffee-ground sediment attached to mucous membrane; mucous membrane of stomach and intestines hemorrhagic in spots though not necrotic.

Injections with the Preventive Toxin.

The Minister of War, complying with the request of the President of the Board of Health, ordered that the prisoners of the Military Prison at Vera Cruz who were willing should receive injections of the yellow fever preventive toxin. Only two of them availed themselves of the opportunity.

Case I.—Enrique Charon, twenty-three years of age, arrived at Vera Cruz eight days ago from Guanajuato. He received on July 19th at 8 A. M., one hypodermic injection of ½ gram of the preventive toxin. Temperature and pulse: 8 A. M., 36.3° C. (97.3° F.), pulse 64, injection; 8 P. M., 37.7° C. (99.9° F.), pulse 88; a light local general reaction.

July 20th: 8 A. M. he received hypodermic injection of 1 gram of the toxin. Temperature and pulse: 8 A. M., 36.7° C. (98.1° F.), pulse 76, injection; 4 P. M., 38.7° C. (101.7° F.), pulse 76. Local reaction slight; general reaction more marked than before, evidenced by moderate fever with uneasiness and slight headache.

July 21st: 8 A. M. he received one injection of 2 grams of toxin. Temperature and pulse: 8 A. M., 37° C. (98.6° F.), pulse 88, injection; 4 P. M., 38.1° C. (100.5° F.), pulse 96. Feverish reaction moderate, affecting pulse more than temperature; headache slight.

July 22d: No injection; temperature, 8 A. M., 37° C. (98.6° F.), pulse 84; at 4 P. M., 36.8° C. (98.3° F.), pulse 76.

July 23d: 8 A. M., received hypodermic injection of 5 grams of toxin. Temperature and pulse: 8 A. M., 36.8° C. (98.3° F.), pulse 80, injection; 8 P. M., 38° C. (100.3° F.), pulse 82. Moderate reaction, slight chills and headache; no pain in the back and no vomiting.

July 24th: Normal condition; temperature at 8 A. M., 37° C., pulse 90.

Case II.—Albert R. Gil, thirty-two years of age. He arrived at Vera Cruz five months ago from Morelia. He received at 8 A. M. of the 19th of July a hypodermic injection of ½ gram of toxin. Temperature and pulse: 8 A. M., 36.4° C. (97.5° F.), pulse 76, injection; 12 M., 36.7° C. (97.9° F.), pulse 88; 8 P. M., 37° C. (98.6° F.), pulse 80. Local reaction; pain and swelling of the place injected, and a very general moderate reaction.

July 24th: The patient received at 8 A. M. a hypodermic injection of 1 gram of toxin. Temperature and pulse: 8 A. M., 36.8° C. (98.3° F.), pulse 68, injection; 4 P. M., 38.4° C. (101.1° F.), pulse 96. The general reaction was more intense than yesterday, with headache.

July 21st: Received an injection of 2 grams of toxin; temperature and pulse: 8 A. M., 36.7° C. (98.1° F.), pulse 76, injection; 4 P. M., 38.9° C. (102° F.), pulse 100. The feverish reaction was still greater, with headache and uneasiness.

July 22d: No albumin in the urine; no injection; temperature and pulse normal. July 23d: He received at 8 A. M. a hypodermic injection of 4½ grams of toxin. Temperature and pulse: 8 A. M., 37° C. (98.6° F.), pulse 90, injection; 4 P. M., 39.2° C. (102.6° F.), pulse 108; 8 P. M., 38.5° C. (101.3° F.), pulse 108. The feverish reaction was greater than that before registered, with more uneasiness and headache; no vomiting; no albumin.

July 24th: Normal condition.

While the experiments lasted Charon and Gil remained at the Military Hospital, and after July 25th they returned to the prison.

I also thought of injection of the toxin in the case of convalescents from yellow fever. In view of the effect of the toxin in the above experiments, made on men who were not immune, I suggested to Dr. Barnard E. Baker that the toxin be tried on men who had been rendered immune by previous attack of the disease, to see whether the reaction observed in the non-immune would differ, especially in the convalescent whose organisms still contained antitoxins. I also thought that in event of the absence of reaction after administering the toxin, there would be proof of the specific character of the bacillus icteroides that secretes the toxin. Nevertheless, Sanarelli demonstrates that the effect of his serum is not due to the existence of antitoxin substances, as in the case of anti-diphtheritic serum, and that dogs, which had been inoculated repeatedly for a year and could stand fatal doses, manifested, nevertheless, at each new injection, symptoms of vomiting, and were in a serious condition. This being the case, the preventive and curative serum of yellow fever, drawn from immune animals inoculated with Sanarelli's bacillus, would, I believe, present an analogy to the serum of typhoid fever, for in this case the preventive and curative action of the serum in animals is not due to the antitoxins, as may be seen from the fact that immune guinea-pigs are more sensible to the action of typhotoxin than the normal animal. This seems to indicate that there is a close analogy between the action of the bacillus icteroides and the pathogenic organism of typhoid fever.

Case I.—Donoteo Solis, twenty-six years of age, of the Eighth Infantry, entered the Military Hospital of Vera Cruz on July 21, 1899, sick with yellow fever. On July 25th, at 8 A. M., being convalescent, he received a hypodermic injection of 2 grams of toxin. Temperature and pulse 8 A. M., 36.7° (98.1° F.), pulse 64, injection; 12 M., 38.8° C. (101.9° F.), pulse 76; 8 P. M. 37.9° C. (100.3° F.), pulse 62. Slight reaction, with little headache and pain in the injected region. At 8 A. M., of the next day, normal conditions.

Case II.—Julio Ronzon, of the Eighteenth Infantry, entered on July 13, 1899, sick with yellow fever. At this date, July 25th, after thirteen days of illness, he is recovering. At 8 A. M. he received a hypodermic injection of 1 gram of toxin. Temperature and pulse: 8 A. M., 36.6° C. (97.9° F.), pulse 80, injection; 12 M., 37.3° C. (99.1° F.), pulse 88; 4 P. M., 38° C. (100.4° F.), pulse 84; 8 P. M., 37.9° (100.3° F.), pulse 100. Slight reaction; headache and pain in the place injected. Normal condition at 8 A. M. of the next day.

Case III.—Antonio Hemandes, sick of yellow fever. Received on the day after his entry a subcutaneous injection of 30 c.c of serum. In the evening temperature ascended to 40° C. (104° F.), and an erythematous eruption appeared, which was mistaken for that of measles. The

later evolution of the disease confirmed the first diagnosis of yellow fever. The eruption was caused by the injection of serum. At 8 A. M. he received an injection of 1 gram of toxin. Temperature and pulse: 8 A. M., 36.8° C. (98.3° F.), pulse 62; injection; 12 M., 37.1° C. (98.8° F.), pulse 56. No reaction.

Case IV.—Martin Mirandi, sixteen years of age, Eighth Infantry, entered the Military Hospital on July 10th, 1899, very sick with yellow fever. He arrived in Vera Cruz fifteen days ago from the City of Mexico. July 26th, he received at 8 A. M. an injection of 2 grams of toxin; temperature and pulse: 8 A. M., 36.8° C. (98.3° F.), pulse 72, injection; 4 P. M., 38° C. (100.4° F.), pulse 68; 8 P. M., 37.6° C. (99.7° F.), pulse 60. Moderate reaction, with a little uneasiness and headache; pain in the place injected. At 8 A. M. of the next day was normal condition.

Case V.—Cristobal Mejia, twenty-three years of age, of the Twenty-third Infantry, arrived at Vera Cruz three months ago from El Corral. Entered the Military Hospital very sick with yellow fever, recovered on this date, July 26, 1899. He received at 8 A. M. a hypodermic injection of 3 grams of the toxin. Temperature and pulse: 8 A. M., 36.8° C. (98.3° F.), pulse 72, injection; 4 P. M., 39.5° C. (103.1° F.), pulse 92; 8 P. M., 38.4° C. (101.1° F.), pulse 90. Intense feverish reaction; severe headache and pain in the place; no vomiting. At 8 A. M.of the next day normal temperature and puise.

Case VI.—Rodrigues (Case I., page 46). He received, July 26, 1899, at 8 A. M., a hypodermic injection of 3 grams of toxin. Temperature and pulse: 8 A. M., 37.7° C. (99° F.), pulse 60, injection; 4 P. M., 39.2° C. (102.6° F.), pulse 80; 8 P. M., 38.4° C. (101.1° F.), pulse 112. Very intense reaction; dry and hot skin; headache; pain in the region injected. At 8 A. M. of the next day, normal condition. To complete the preceding experiments it should be added that the blood of Guevara (Case VI.) and that of another patient of yellow fever, at the Military Hospital, did not show the agglutinating reaction of Widal in the cultures of Sanarelli's bacillus.

Conclusions.

1. Both intravenous and subcutaneous injections of the serum produce a general reaction, revealed by the hyperthermia and acceleration of the pulse.

2. The injections, both subcutaneous and intravenous, neither controlled the disease nor manifested in the patient the least reaction upon the appearance, development or duration of the symptoms of yellow fever.

3. It is not possible to form conclusions on the inoculation of the preventive toxin on account of the small number of cases and the short time employed.

4. The reaction caused by the injections of the toxin in the convalescents of yellow fever demonstrates Sanarelli's assertion that the curative powers of the serum, in animals, is not due to the antitoxin substances; and confirms by its analogy to the typhoid serum the opinion, given by some bacteriologists, that the icteroides is an Eberthiform bacillus.

REPORT OF A CASE OF SCORBUTUS IN AN INFANT.[1]

BY WALTER LESTER CARR, M.D.,
OF NEW YORK.

THIS report of a case of scorbutus in an infant may not present anything that is new, but the history is interesting in its clinical points.

A. H., female, twelve months of age, was brought to me because her mother felt that the baby was failing and that she had rheumatism or some disease that gave her a great deal of pain. The mother was delicate and anemic, with a negative family history. Both mother and father were Americans. An older child was rachitic. The hygienic surroundings were good.

The baby was born in the summer, when the mother was away from home. She was able to nurse the baby for only one week, when cow's milk was tried, but it was vomited and did not agree with the baby. Carnrick's soluble food with cow's milk was tried with fair result for one month, when the food alone was given for four weeks. Mellin's food, Imperial granum, peptonized milk, and kumiss were used for varying periods of three to seven weeks, but as each failed to agree with the baby a change was made. Barley water, with cream and milk-sugar, was tried for four weeks. Occasionally beef-juice was added to the other food. Eskay's food was given for the longest period—five months—but as the baby had diarrhea, with loose, slimy movements, the Carnrick food was administered during the summer. The baby had also bread, butter, and crackers. Occasionally she had a small amount of milk, but it was usually vomited or caused diarrhea. The white of an egg was sometimes the only food that was borne by the stomach. The baby had colic from the time she was six weeks old, and was also restless and uneasy. Dentition began when she was nine months old. She never tried to walk. Bronchitis as the result of an attack of "the grip" gave the baby a great deal of trouble. The mother said that for three weeks the baby had been restless and uneasy, and would cry out as if in pain. She did not sleep well and cried when the clothing was changed or when she was taken up. The movements of the bowels had been offensive, but did not contain blood. There had been no eruption or hemorrhage.

On my approach the baby began to cry, and gave every indication, by her expression, of suffering and fear. She was emaciated, poorly nourished, and weighed only eleven pounds. When the mother took off the clothing the baby showed

[1] Read before the Section on Pediatrics, New York Academy of Medicine, October, 1899.

her thighs and legs semi-flexed. There was swelling over the lower third of the left thigh that did not extend into the joint. There was no heat, redness, or edema. The right thigh did not give as manifest signs, but it was tender and there was thickening under the periosteum. There was swelling around the ankles and tenderness above the malleoli. The mother thought these symptoms less evident than they were a few days before. All other joints and bones were normal. The skin was mottled, but had no hemorrhagic or petechial spots. The skin at the back of the head was moist. The mucous membrane of the mouth was reddened and the gums over the lateral incisors were dark blue and swollen so that the teeth could not be seen. There were four upper incisors but the swelling covered the two lateral ones. There was no hemorrhage from the gums. The tongue was quite clean and the mucous membrane did not exhibit any hemorrhagic areas.

The liver, spleen, and heart were normal; the lungs were affected by a slight bronchitis; the urine contained phosphates, but no albumin or blood. The blood was not examined. No further evidence was needed to show the disease to be scorbutus from improper food, although the rachitic signs were not as marked as in some cases of scorbutus in infants. Beef-juice, orange-juice, and a small quantity of fresh milk were ordered. A prescription for an opiate was written so that it could be used for excessive pain and restlessness.

In three days there were few signs of the scurvy. There was still a thickening of the left thigh but the baby could sit in a high chair, and rested well. The gums were not reddened or swollen. There was no interruption to the recovery and the opiate did not have to be administered. The satisfactory result of the anti-scorbutic diet was shown by the willingness of the baby to move the legs and thighs. The relief from pain came almost as soon as it could have been accomplished by doses of opium.

Discussion.

Dr. Koplik: The most important symptom of scurvy is the limitation of movement. This is, of course, due to the pain. The apparent paresis that results from the fact that any movement causes pain leads to all the mistakes of diagnosis. It is the first symptom that occurs at a very early stage of the disease, and if it at once leads to suspicion as to its real cause the diagnosis will usually be easy. Any limitation of movement then that occurs in small children, especially if they have been fed to a large extent on prepared foods, should at once lead to careful examination. In my experience it is necessary to use some sort of fruit juice in the treatment. Milk and meat juice do not suffice. I have had the best results with orange juice, which is always easily obtainable.

Dr. Abraham Jacobi: Some cases of scurvy in children begin with very unusual symptoms, and it is necessary for the physician to be on his guard in order not to mistake them. For instance, I have had two cases in which hematuria was the only symptom. It began without warning, and at first there seemed to be nothing else that would lead one to suspect the presence of scorbutus. After careful search I found a slight lividity of the gum over the central incisors, and also some petechiæ. It is the immobility of these cases that gives rise to errors of diagnosis. It is mistakenly considered to be a symptom of two diseases in particular, acute anterior poliomyelitis and acute rheumatism. As for poliomyelitis there is no excuse for the error of diagnosis, for it is immobility from pain not inability to use the limbs that is present. For rheumatism there is perhaps more excuse, but usually in scurvy the joints are not affected, and if the limb is supported the joint may be moved without causing pain. Very rarely in scurvy are there hemorrhages into the joints, in which case, of course, the similarity with rheumatism is very marked. As a rule, however, there are very few exceptions, the lesions of scurvy in the bone are subperiosteal hemorrhages in the diaphysis of the long bones.

Dr. Heiman: The blood picture in scurvy is very similar to that of secondary pernicious anemia. There is a poikilocytosis, and a number of nucleated red corpuscles are noted. The red cells are very irregular in shape, and there are many microcytes and macrocytes.

Dr. Koplik: I have seen certain cases of hemorrhagic rachitis which it would be easy to mistake for scurvy. In a case of scurvy which I saw recently there were the thickened bone-ends that made me think of rickets, but the case cleared up completely on antiscorbutic treatment.

Dr. Carr, in closing: A few years ago these cases were very generally missed, but the study of scurvy has made it comparatively easy to recognize them now if the practitioner be only on the lookout for them.

CLINICAL LECTURE.

MYOMECTOMY PER VAGINAM COMBINED WITH SHORTENING THE ROUND LIGAMENTS FOR RETROVERSION, ETC.[1]

By J. RIDDLE GOFFE, M.D.,
OF NEW YORK.

ATTENDING GYNECOLOGIST TO THE NEW YORK CITY HOSPITAL; PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

Case I.—I shall bring before you this morning two cases. The first patient is a woman forty-three years of age, with the following history: She has been married twelve years and had one child eight years ago. Within two years thereafter she had two miscarriages, both of which

[1] A clinical lecture delivered at the New York Polyclinic Medical School and Hospital, December 8, 1899.

were artificially induced. Since that time she has been suffering from backache, irritable bladder, and irregular menstruation. She says that during the past three months she has menstruated profusely six times.

Upon examination, as you may remember at our last clinic, we found a retroverted uterus and prolapsed appendages of both sides, all being firmly bound down by adhesions. We also noticed that just above the waist of the uterus in its posterior surface, there was a round, hard body which suggested either a sharp flexure of the uterus or a fibroid in its posterior wall. We have before us, then, a case of retrodisplaced uterus, with such firm adhesions as to preclude the possibility of accomplishing relief by any form of treatment short of surgical interference.

The surgical procedures that have been recommended and applied for the relief of this condition are manifold, and it becomes necessary, therefore, to choose that method which especially commends itself to the operator as applicable to the case in hand. The operations most popular at the present time are (1) abdominal incision through which the uterus and appendages are set free, and the displacement relieved by stitching the uterus to the abdominal wall; (2) shortening the round ligaments, or what is commonly known as the Alexander operation, and (3) anterior colpotomy, or the opening into the pelvic cavity through the anterior vaginal fornix, the breaking up of adhesions, and the relief of the displacement by shortening the uterine ligaments.

The first operation, while it is easy of accomplishment and is usually successful in holding the uterus in an anteverted position, has fallen into disfavor on account of the serious complications attending parturition after its employment. The operation, moreover, necessitates a laparotomy, which by conservative men is regarded as too serious a procedure for the relief of this condition. The Alexander operation at present is probably the most popular procedure for the relief of retrodisplacement. It has the disadvantage, however, of having a limited field of application, being indicated only in cases of simple retroversion in which the pelvis is free from adhesions and the appendages free from disease. Moreover, about 5 per cent. of the cases subjected to this operation suffer from hernia, single or double; in another 5 per cent. the round ligaments cannot be found, and, in all, the patients bear upon their persons two unsightly scars. It is only fair to say in this connection, however, that the field of operation has been extended to include cases of adherent uteri by first opening the posterior fornix vaginæ and setting the organs free by breaking up the adhesions.

The third operation, namely, the opening of the anterior fornix of the vagina and shortening the uterine ligaments through the opening, is the one that especially commends itself to me and the one which I shall apply in this case. The readiness with which this incision permits of treating the various common conditions which we find in the pelvis will be illustrated in the case before us, and as the patient is ready, I will proceed to give you a demonstration of the advantages of this mode of procedure rather than spend further time in dilating upon them. Working upon the principle that disease in the appendages has its early seat in the mucous membrane of the uterus, it is the invariable custom to make sure that the interior of the uterus is relieved of diseased conditions in all these cases to avoid any possible return of the disease. With the patient on the back, the hips well drawn down to the end of the table, as you see, I apply a self-retaining posterior retractor, thus bringing the cervix into view, which I catch by the anterior lip with bullet forceps. The cervix is then dilated until it will admit a sharp curette, which I now pass and go over the entire surface of the uterus, scraping away all soft and spongy tissue. The uterus is then irrigated through the cervical cannula with bichloride (1-3000), and then with normal salt solution. Through this same tube I pack the uterus comfortably full with a narrow strip of iodoform gauze. I now seize the cervix with the volsellum forceps, and make a transverse incision through the vaginal wall in front of the cervix corresponding to the first incision in the vaginal hysterectomy; through this I dissect off the the bladder from the uterus by dull dissection with the handle of the scalpel and with my finger until I reach the reflection of the peritoneum. Catching the edges of the vaginal incision near the middle point with the artery clamps, I draw down until the anterior vaginal wall is made taut, and then make a longitudinal incision throughout its entire length, beginning at the middle point of the transverse incision. The bladder is then dissected from the vaginal wall on either side of this incision for a distance of three-quarters of an inch. Removing the forceps and forcing my finger through the peritoneum at its reflection from the bladder to the uterus, and tearing it either side, I have a large, free opening through which to manipulate.

Passing my index finger along the anterior wall of the uterus and over the fundus, I find a false membrane reaching from the fundus to the rectum and stretched out either side along the free border of the broad ligaments, covering over the appendages of both sides. Keeping my finger in contact with the uterus, I thrust it through this membrane and strip off either side; this sets the uterus free, and by hooking my finger over the broad ligament near the horn of the uterus and forcing the cervix back into the posterior fornix of the vagina, by a little manipulation, as you see, I antevert the uterus and deliver it into the vagina.

I now remove the forceps from the cervix, and dragging the fundus of the uterus a little lower down, with my thumb and finger, I find the enlargement in the posterior wall, as you see, to be a fibroid tumor about the size of a hen's egg. By breaking up the adhesions about the appendages I set them free and am able to draw them down into the vagina for examination.

I think from where you sit you can all see that these appendages, excepting where I have torn away the adhesions, seem perfectly normal. By passing this small silver probe into the Fallopian tubes we find them patulous throughout their entire extent. As the ovaries are healthy, no operative interference is indicated and we return them to the pelvic cavity. The relaxation of the ligaments maintained during these four or five years by the retroversion, give the uterus, now that the adhesions are broken up, unusual mobility, and I am able to draw the fundus well down to the vulva, and with this bright sunlight falling directly upon its posterior wall, I will proceed to remove the fibroid or do what we know as myomectomy.

I make a longitudinal incision through the peritoneum, the muscular wall of the uterus, and the capsule of the tumor. Using the handle of the scalpel, I readily shell out the tumor from its capsule, and we have, as you see, a solid fibroid mass. I now sew together the muscular wall of the uterus with a buried catgut suture, taking care by using sufficient force to draw the muscles taut over the gauze packing which fills the uterus. To avoid any raw surface upon the uterus and the danger of adhesions therefrom, I apply now four Lembert sutures of fine silk to close the incision through the peritoneum of the uterus.

We have now relieved the patient of the fibroid tumor, which, no doubt, was the cause of her frequent and excessive menstruation; we have set the uterus and its appendages free, and it now remains to shorten the round ligaments in order to maintain the uterus in its normal position. Rotating the uterus slightly upon its longitudinal axis, I catch the round ligament with an artery clamp about 1½ inches in this case from the uterus. Making traction upon the forceps I form a loop in the round ligament, the edges of which I stitch together with three sutures of fine silk. To dispose of this loop in the round ligament and further assist in maintaining its supporting power, I pass another silk suture through the point caught in the forceps and again through the fibers of the round ligament as they spring from the side of the uterus and pin it there by tying the suture. The round ligament of the opposite side is shortened in the same way, as much slack being taken as can be obtained.

The bladder is now restored to its normal position, and the longitudinal incision of the vagina closed by a running catgut suture; the transverse incision is left to take care of itself, although in some instances I also close that in the same way. A little gauze pack in the vagina completes the dressing, and a self-retaining soft rubber catheter passed into the bladder makes the patient ready for bed.

Case II.—In order that you may see the result of this vaginal work, I now show you a woman upon whom I operated one week ago. She appeared at the clinic with the following history: Age, thirty-four years; married twelve years, and the mother of two children, the youngest six years of age. She has suffered since her last confinement with severe and almost constant backache, pain over both ovarian regions, and a general ill health. Examination revealed a retroverted, adherent uterus, with prolapse of the appendages of both sides. Upon opening into the pelvis through the anterior vaginal fornix firm adhesions were found to exist on all sides, binding down the uterus and appendages, that were so extensive and reached down so low in Douglas' pouch that it seemed best to open Douglas' culde-sac to assist in breaking them up. The uterus and appendages were then delivered through the anterior incision into the vagina; the left appendages were found to be hopelessly diseased and were removed (as you will remember). Upon the right side we found a comparatively healthy ovary, but a club-shaped, occluded tube, with disease in its outer third; the tube, was, therefore, amputated at its middle point, the mucous membrane lining it stitched to the peritoneal covering around the entire circumference of the opening. This stump of tube was then attached near to the ovary and returned to the pelvis. After this the round ligaments of both sides were shortened by the method you have seen me employ to-day, and the uterus returned to its normal position in the pelvis. The operation was completed, as in the case that has just left us, with the exception that I passed some gauze into Douglas' pouch for drainage. The patient looks bright and cheerful, as you see, and tells us that she has had no pain since the operation, and is feeling well. This patient will be allowed to sit up at the end of the second week, and leave the hospital at the end of the third week. One of the advantages of this route of attack in cases of pelvic disease is the smooth and comfortable convalescence; there are no stitches to be removed, no adhesive plaster to be worn, and no abdominal supporters to annoy the patient for six months or a year; and yet in these two cases which we have seen this morning I have dealt with a variety of conditions in the pelvis that are thought by many to be satisfactorily dealt with only through an abdominal incision. An abdominal incision is a great misfortune to befall any woman, and, in my opinion, never should be resorted to in pelvic disease until an effort to relieve by the vaginal method has been tried and found to be impracticable.

MEDICAL PROGRESS.

Gangrene of Intestine.—A. E. Barker reports (*British Med. Journ.*, Dec. 23, 1899) two cases of primary enterostomy. In one case he removed about thirty inches of gangrenous small intestine and in the other about twelve inches. In both cases circular enterorrhaphy was performed by means of continuous silk sutures. In both patients the strangulation had occurred in an inguinal hernial sac. The writer says that the

stomach should be washed clean with hot water and a little brandy before operation, and the patient should be well wrapped in flannel. During the operation a large enema of hot water and brandy should be given and hot saline solution should be injected hypodermically from time to time to make good the loss of fluid by vomiting, sweating, and respiration. Local analgesia with beta-eucain is advisable except for very nervous patients. These should be given chloroform. His further advice is to draw the affected loop well out until healthy tissue is in hand, empty the gut, and compress it with clamps; surround it with gauze and divide it. The cut through the lower limb may be made obliquely, so as to make the opening correspond in size to that of the upper distended limb. Close with a Murphy button or suture. Wash the gut with saline solution before returning it. Use no germicides on the intestine. If the sac is gangrenous use gauze drainage; otherwise the hernial sac may be obliterated and the ring sutured. Nutritive enemata alternating with hot-water enemata should be given every four hours.

Treatment of Tuberculous Peritonitis.—W. Cheyne (*Lancet,* Dec. 23, 1899) says that tuberculosis of the peritoneum appears clinically in three forms. The peritoneum may be studded with small tubercles scattered irregularly over its surface, without the formation of adhersions or omental contractions, and with or without fluid, which, if present, is either straw-colored or tinged with blood. When the finger is inserted into a peritoneal cavity in this condition it feels as if it had been pushed into a bag of boiled sago. Secondly, the tubercles may be in a condition of fibroid induration, with a matting together of the intestines and other viscera and a shrinking of the omentum. The mesenteric glands are enlarged but are not cheesy, and fluid if present is usually encapsulated. In the third condition of peritoneal tuberculosis the glands are greatly enlarged and caseated, and there are adhesions and contractions. The fluid is encapsulated and not infrequently purulent. It is a curious fact that more women are operated upon for this trouble than men, while at autopsy it is much more common in men. This may be in part explained by the fact that it is often discovered in women after a laparotomy has been performed for some other cause. Mortality is greatest in the caseous form of the disease and least in the dry adhesive form. In this form it is from 14 to 17 per cent. A study of operations upon 385 patients showed that 31 (8 per cent.) died from the immediate effects of operation, while 51 (13 per cent.) died within eighteen months from extension of the disease, and 53 (14 per cent.) were quite well two years after operation. A considerable number of the patients could not be traced, but making all due allowance for them it is undoubtedly safe to say that 50 per cent. of the patients operated upon for tuberculous peritonitis are cured. If medical measures fail to give relief in chronic cases in from four to six months, or in acute cases in from four to six weeks, the patient should be advised to undergo an operation. There is a disadavantage in operating too early, however, since recurrence seems more likely to follow under those circumstances. Unless easily gotten at, tubercular organs should not be removed. Evacuation of fluid by aspiration has not proved successful in curing tuberculous peritonitis, and it carries with it the risk of fatal puncture of the intestine. The best operation is a simple incision without the use of germicides or flushing of the abdomen. Firm adhesions should not be separated, but if there is intestinal obstruction anastomosis may be performed. If a pus-sac is opened it should be washed out. No drainage should be employed either in the presence of serous or purulent fluid. Improvement sometimes follows operation immediately and sometimes it begins after a lapse of ten days. Cheyne looks upon the improvement as similar to that which follows the opening of an abscess and evacuation of its pus. When the fluid is removed serum is poured out. Owing to the long continuance of the infection, the serum of the body has attained a certain bactericidal power which after operation is exerted upon the organisms in the cavity into which the serum is poured. This theory expains why a too early operation fails to stop the disease, for the serum at so early a stage may be supposed not to possess a sufficient antitoxin strength. Be the cause of improvement what it may, at a later period after operation the peritoneum is often found smooth, no adhesions being present. There is a favorable time to operate—not too early and not too late—after the formation of fluid and before adhesions become firm.

Transmission of Albuminuria.—M. Carrière (*Gaz. Hebd de Med. et Chir.,* Dec. 14, 1899) has observed a marked heredity in the children of albuminuric patients. In support of his opinion he cites the case of a patient, who, in the eighth month of pregnancy, presented marked albuminuria. She was at once placed on a milk diet, which, although it did not remove the albumin, checked the progress of the condition. Labor supervened, and on examining the urine of the child nineteen hours after birth, traces of albumin were found. A second examination, made twelve hours after the child was put to the breast, gave negative results. Investigation showed that the condition of the mother was probably chronic, dating back nineteen years to an attack of scarlatina in childhood. Carrière believes that the condition of the urine of the infant may be fairly taken to indicate a congenital renal lesion.

Mitral Stenosis and Air-Cure.—Mitral stenosis, as A. Surmount (*Gaz. Hebd. de Med. et Chir.,* Dec. 14, 1899) points out, may long exist without fatal result, provided one is careful to demand no greater labor of the impaired organ than it is capable of performing. It is especially necessary to prevent pulmonary complications and to

this end an air-cure is recommended. Four years of personal experience has proven the therapeutic value of this measure to be truly surprising. The method must be followed constantly, day and night; conditions of the weather, even in northerly climates, offering but rare exceptions. He cites the case of a patient who for the last two and one-half years has never slept with the windows of her bedroom closed. Absolute repose is prescribed only so far as is needed to avoid heart-fatigue. Diet is to be adapted to the state of the digestive system. Over-alimentation is avoided as it is not desirable for the patient to take on fat. Under the influence of the air-cure pulmonary troubles rapidly amend, the troublesome asthma disappears, bronchitis is less frequent, the state of the heart improves with the disappearance of these complications, the pulse becomes regular, full and less rapid, the mitral stenosis in fact ceases to be a malady and once more becomes a simple cardiac malformation.

Acromegaly and Raynaud's Disease.—Of more than usual interest is A. Boettiger's article (*Münch. Med. Woch.*, Dec. 19, 1899) giving an account of a case in which both these rare maladies were present. The patient, twenty-one years of age, noticed as first symptoms, coldness, numbness and formication in the hands and feet which soon turned a dark-blue color. Neuralgic pains were absent. The paresthesiæ and discoloration, at first paroxysmal, soon became more intense and persistent. The patient's attention was soon attracted to an increase in size of the hands and head. Symptoms of intracranial pressure, eye-disturbances or rheumatic pains were absent, nor could any retinal or other ocular changes be demonstrated. The tongue was wider, the nose thicker, and a radiograph showed a decided increase in volume of the bones, and more particularly of the soft parts of the right arm and left hand. The skin of the palm was tough, hypertrophied and showed excessive cornification; the hands themselves were cold and moist, but the most prominent symptom was the bluish-black discoloration, mottled with a few irregular reddish spots, and extending above the wrists. The sensation of touch was perfectly normal, but pain was elicited only on penetrating for some distance into the skin. The susceptibility to heat and cold was much diminished. In discussing the case the author says that it is not the first one of its kind; indeed, there often are peripheral vasomotor neuroses in the beginning stages of acromegaly. There are, in short, close relations between the latter disorder and Raynaud's disease, since stasis is not rare in the one and swelling and thickening may occur in the other. In both the seat (hands, feet, nose, ears and later arms and legs) is the same, and similar pathologic vessel changes have been discovered. Boettiger does not believe in the hypophysis theory of acromegaly, but on the basis of the cited case develops a new explanation. It sems to him illogical to refer so general a disease to so small an organ; then, too, the fact that the pituitary body is so often diseased without acromegaly being present, and that symptoms directly referable to this body may be wanting in gigantism, make him conclude that the general belief is untenable. There are many arguments which favor the view that acromegaly is not caused by pituitary tumor. While there may be a certain relationship between the rapidity of growth of the latter and the amount of thickening in the bones, this is by no means constant. Granted that this disorder does not depend on a specific internal secretion, a cause for the hypophyseal hypertrophy must be sought. It is a well-known fact that poisons in the circulation, such as arsenic, alcohol, lead, etc., can cause changes in the peripheral parts of the body. There are also diseases dependent on the production within the body in some unknown way of toxin which can lead to vasomotor and trophic disturbances at the same sites. Raynaud's disease has been considered as such. It is probable that, due to heredity, constitution, diet, etc., toxins may be produced which have a selective action on certain tissues. Thus arthritis deformans and hypertrophic pulmonary arthropathy involve the bones; chemical poisons, diphtheria, etc., the nerves; scleroderma and myxedema, the skin, etc. Acromegaly also begins in the periphery and at its outset there may be symptoms of Raynaud's disease; it thus seems likely that leucomaines are the essential cause. The analogy is further borne out by the cerebral symptoms which suggest a toxemia. But where do these toxins come from? Most, no doubt, would say the hypophysis, but for this Boettiger thinks there is no proof. The case described was put on vegetable diet and treated with iodin, hydrotherapy, peripheral faradization and central galvanization with the most encouraging results.

Mercurial Inunctions.—Before a meeting of the Naturforscher und Aerzte in Munich Schuster (*Wien. Med. Blat.*, Dec. 21, 1899) read an article on the method of absorption of mercury when given in inunction. It has been stated far and wide that these inunctions simply produce a vapor of mercury about the patient which is constantly inspired with each breath and thence passed through the system. Schuster experimented upon himself with a view of determining the truth of this statement. He remained in bed for fourteen hours a day during two weeks, covered with a sack which had been prepared with blue ointment, as recommended by Welander. An examination of the urine showed the presence of mercuric iodid. After this, on nine successive evenings, he rapidly rubbed his thigh with the ointment, covering the area thus treated with parchment paper and rubber tissue, and then with a flat spatula he beat the dressings to facilitate the entrance of the mercury into the pores of the skin. Three gauze bandages completed the dressing and prevented its slipping. After wear-

ing this for six hours, he removed the ointment each morning by means of cotton saturated with benzine. After this course of treatment, which did not permit of his absorbing the mercury by means of the lungs, he examined his urine and again found the mercuric iodid ring. Thus he proved satisfactorily that although the lungs may assist in the absorptive process, the skin undoubtedly does its share of the work.

Typhoid and Colon Bacilli.—A series of experiments has been undertaken by E. Unger and E. Portner (*Münch. Med. Woch.*, Dec. 19, 1899) to ascertain the value of Piorkowski's new method. The culture medium consists of urine which has been allowed to turn alkaline by remaining in the thermostat for two days, 3.3 per cent. gelatine and 0.5 per cent. peptone being then added and the mixture sterilized at 100° C. Seventeen hours after inoculation the following results were obtained: The colon bacillus formed circular, sharply circumscribed, light-brown colonies, while those of the typhoid germ appeared small, clear, colorless, oval or quadrangular, with numerous single or branching filaments three or four times longer than the body itself, or they may be shorter or longer. If allowed to grow longer at 22° C., the coli colonies will develop more rapidly, while in thirty-six hours the typhoid colonies will lose their transparency, take on a yellowish-brown color and elongate, their filaments not increasing much but becoming broader, more granular and surrounding the central body in a network. Differentiation, then, becomes more difficult. While the characteristic typhoid colonies invariably yield typhoid bacilli, colonies are not always obtained and a number of similar colonies of bacilli with shorter filaments are often seen, which may yield the bacillus coli, and are also obtained in the stools of diseases other than typhoid. The authors formulate the following rules: (1) Bodies with no filaments show that there is no typhoid present. (2) If bodies with long filaments are present the diagnosis of typhoid may be made. (3) Short-filamented colonies plus the clinical signs of typhoid point toward this fever, but without these symptoms the diagnosis is in doubt. The new culture-medium is, furthermore, valuable as but from two to three days are required to determine a diagnosis. By its use the earliest bacilli are found on the second day of the disease, and during its course their number will be in proportion to the severity of the diarrhea. They usually disappear on the eighth to the tenth day of convalescence, but have been seen five weeks after the subsidence of the fever. During a relapse they reappear sometimes in pure cultures. Blood from the roseola spots gives negative results, but in the urine they can be readily demonstrated, and the authors reach the conclusion that the existence of a true nephritis is not necessary to explain their presence there. Stab cultures made with the culture-medium show that the typhoid bacillus gives grayish lines with fine lateral branches, while the coli growths are larger and more sharply defined.

Analysis of Gastric Contents.—H. F. Hewes (*Boston Med. and Surg. Jour.*, Jan. 4, 1900) presents a new and simple method of quantitative analysis of the gastric contents for use in clinical work. The steps are as follows: (1) *Total free HCl.*—To 5 c.c. of unfiltered contents in a test-tube add a few drops of Töpfer's reagent. If free HCl. is present the mixture will assume a carmine-red color. To this add a decinormal solution of sodic hydrate by titration until the carmine changes to an orange, or a bright yellow. Multiply the number of cubic centimeters of the soda solution necessary to cause this change by .00365 gram, and the result is the amount of free HCl. in the 5 c.c. of contents. (2) *Total free Acids plus Acid Salts.*—To the same mixture continue to add the decinormal soda solution until a drop of the mixture fails to color Congo-red paper. All the free acids and acid salts are now neutralized. From the quantity of soda used up to this point the quantity of free acids plus acid salts in the contents can be estimated in the same manner as in the estimation of the free HCl. (3) *Total Acidity.*—To this neutralized mixture add two drops of a one per cent. alcoholic solution of phenophthalein. Continue to add the soda solution until a deep red of maximum intensity is obtained. The deep red color indicates an alkaline reaction. From the total quantity of soda solution used in neutralizing all acid elements the total acidity can be estimated. Now the quantity of total organic acids plus acid salts is obtained by subtracting the results of Test 1 from the results of Test 2. By subtracting the results of Test 2 from the results of Test 3 there is obtained the total combined acids, and by adding this result to the results of Test 1 the secreted HCl. is obtained. Hewes also gives methods of analysis when there is no free HCl. present, and the details of a test for combined HCl. when such is the case. Hewes uses these methods as a routine in his clinics in all cases of gastric affection.

Diphtheria.—Statistics in regard to diphtheria in the general hospital at Solothurn in Switzerland, from January 1, 1896, until August 15, 1899, have been compiled by Aug. Walker (*Correspond.-Blatt. f. Schweizer Aerzte*, Dec. 15, 1899) as follows: The mortality rate is still high, being 15.8 per cent. in the 315 cases reported. This statement must be modified, however, when it is seen that tracheotomy had to be resorted to in 177 cases, and that in these cases alone the mortality was 22.6 per cent. This high mortality is due to the large number of cases under one year of age in which the disease was already far advanced and in which the antitoxin serum has been found not as efficient as in older cases. Of the remaining 138 unoperated cases only 15 died —a mortality of about 11 per cent. These included both the simplest cases and the most advanced and dangerous cases in which it was too

late to resort to tracheotomy. Even the death rate of the cases operated on (22 per cent.) should not be considered high, for so low a rate has never been attained before the serum treatment was introduced. At that time the mortality was frequently over 55 per cent.

A curious observation made by the author is that the worst cases came in from the outlying villages, while those from the city itself were both less severe and less persistent. There were many cases in which there was little or no fever. A temperature of 38° or 39° C. was the rule, while higher fever than this indicated always belonged to the worst cases and made the prognosis grave. Especially was this true if the temperature remained up for a long time as it indicated a severe accompanying bronchopneumonia. Cardiac weakness was seen less frequently than bronchopneumonia. In these cases the temperature is either normal or it sinks to a subnormal point, and the accompanying asthenia may at the slightest movement, such as the lifting of the child, lead to immediate collapse and death. The hemorrhage following tracheotomy is also extremely dangerous to the life of the patient. The paralyses, about which so much has been said and written as to their increase after the use of the antitoxin, did not occur with any greater frequency than before the use of the serum. Untoward results due to serum-therapy were seldom observed. No abcesses were produced thereby and exanthemata very seldom. In four cases a pemphigus eruption was observed, but all were cured of it—one however, dying from a complicating pneumonia. Intubation is not practised by the author and therefore no statistics regarding it are forthcoming.

Lupus Treated by X-rays.—P. M. Jones (*Phila. Med. Jour.*, Jan. 6, 1900) reports two cases of lupus treated by x-rays, one of which he thinks is the first so treated in this country. The first patient, a man fifty-five years of age, had had lupus on his right forehead for twelve years. He had been treated by the actual cautery, curetting, applications of creosote, silver nitrate, hydrogen dioxide, and by many other methods, which caused the lupus to heal temporarily. Later it would break down, ulcerate, and again heal. Each time it returned it was a little larger. At the time the x-ray treatment was begun the involved area was about one and one-half inches long by one-half inch wide. There were three ulcerating points. A sheet of lead was so cut as to protect all of the head except the lupus area. The hole in the lead was cut so as to protect one of the ulcerating points, as a control on the treatment. The patient was exposed four to six inches from a "soft" vacuum tube two to three times a week, the exposures lasting two to five minutes. At the end of four weeks the whole area was healed, with the exception of the one ulcer which had been protected. This was then exposed and was healed in three weeks. The lesion has remained healed. The second patient had had the disease thirty-five years. The whole right side of the face, including the ear, was involved when the treatment by x-rays was begun. The method of treatment was the same as in the previous case, but the exposures were a little longer, averaging five minutes each. Twice an inflammatory condition was caused by the exposures and treatment was suspended. A marked improvement was apparent each time as the inflammation subsided. The ear, being protected from the x-rays, remained unchanged, but the rest of the face improved and healed for the first time in twenty years. The writer is now treating the ear with the result that it has decreased in size and ulceration has ceased. The rays from a "soft" tube are more easily absorbed by the skin, and so are more efficacious in treating lupus. Jones believes that the method of treatment by ultra-violet light (Finsen) will prove better and more rapid than by x-rays.

Ophthalmia Neonatorum.—It was formerly considered that the cause of ophthalmia neonatorum was an improper exposure of the eyes of the child to light. It is now thought that its origin is nearly always gonorrheal, and that the infection comes from the maternal passages during parturition. The disease appears at any time between the second and eighth day after birth, therefore D. S. Reynolds (*Jour. Am. Med. Assoc.*, Jan. 6, 1900) holds that this fact contradicts the theory that the eyes are infected during delivery. Moreover, the staphylococcus aureus procreates in culture media within twenty-four hours, and in by far the greater number of cases the inflammation is due to its development—not to gonorrheal infection. The writer is thoroughly convinced that infection is due to unskilled attempts at washing the child's face or to meddling with its eyes. As to treatment, if seen in the earliest stage, a collyrium composed of sodium borate, grs. x; sodium chlor., grs. iii; ac. carbolic (cryst.) gr. ¼; distilled water, ʒi. should be used, 1 drop being instilled into the affected eye every half hour. When the discharge becomes purulent the same solution should be used with an irrigator, night and day, every half or every quarter of an hour according to the profuseness of the discharge. In cases of undoubted gonorrheal origin the irrigating fluid should consist if sodium chlor., ʒiii; bichloride of mercury, grs. iv; ac. carbolic, grs. xvi; water Oi. If there is extensive swelling of the upper lid a free canthotomy should be done, so that the lid can be everted and the eye thoroughly washed with the irrigator. In conclusion, Reynolds decides that the disease is always the result of contagion, the eye being infected during an attempt at practising Credé's method of prevention, or by the unclean hands of a nurse. The only way to prevent the disease is to avoid infection. The writer condemns very strongly the method of Credé of instilling nitrate of silver solution. When one eye alone is infected the well eye should be protected by a well-fitted watch-glass. Care should

be taken not to cause any abrasions of the cornea, and inflammatory matter not removed by the irrigation should not be removed by any other means.

Diet in Typhoid.—Until recently the feeding of typhoid patients on a simple fluid diet has been so generally and uniformly accepted that physicians have learned to give the stereotyped milk diet without making any attempt to allow a more varied and extended regimen. During the last few years investigations have been made along these lines by several prominent physicians, among whom are Bushuyev, Shattuck, and Fitz. Morris Manges (*Med. Rec.*, Jan. 6, 1900) has given a review of the results obtained by the above investigators and has also reported his own somewhat limited experience in eight cases. Bushuyev treated eighty cases in the year 1896-1897, allowing a full diet, while another attending the same hospital (Russian) allowed only a diet of milk and one or two soft-boiled eggs to a series of seventy-four patients. The percentages in regard to deaths, recoveries, hemorrhages, and perforations, and the general conditions of the patients were slightly in favor of the series treated with a full diet. During the year 1897 he treated 318 patients, losing 26, or a percentage of 8.2. In addition to liquids, such as milk, tea, coffee, cocoa, and soups, he allowed solid foods, such as chicken, boiled meats, cutlets, and bread. In fact, he attempted to stimulate the appetite by a variety of palatable foods. Drs. Shattuck and Fitz of Boston have also obtained results which are signally striking and favorable. They, however, do not advise eating everything, but insist that the patient and not the disease be treated, and that he be fed with reference to his digestive power and not with reference to his fever. Special stress is laid upon the point that typhoid is a general toxemia and it is to this rather than any particular lesion that attention must be directed and the diet regulated. It is urged that the general nutrition must be maintained just as in cases of fever due to tuberculosis and suppurative germs, for the disease is one of considerable duration, and liquid food alone cannot replace the enormous waste. The fear of hemorrhage and intestinal perforation seems to be the cause of the restricted diet, according to most authorities, but it is maintained by the advocates of a full diet that the food is so changed by digestion, before it reaches the seat of typhoid ulcers, that it would have no more local effect than milk. The cause of a perforation is not the character of the food but the nature of the ulcer, since one never hears of the perforation of a tuberculous ulcer due to food. It is also urged that diarrhea and tympanities are increased by solids, but Bushuyev and Shattuck especially note that many of their patients were constipated. The determination of how many relapses may be due to the administration of solids is extremely difficult for the causes of this unfortunate condition are merely conjectured. The consensus of opinion seems to be that they are oftentimes due to the too early administration of solids, but the proportion of relapses in the cases reported by the several investigators was by no means larger than usual. The good results obtained in the cases in which this method of treatment has been tried certainly justified further experiments along the lines of a more extended and varied diet.

Influenza and Endocarditis.—In a meeting held on December 15, 1899, Jehle (*Wien. Med. Blät.*, Dec. 21, 1899) reported several cases of endocarditis in which he found influenza bacilli. Heretofore these bacilli have been found present in the kidney, in the spleen, in meningeal fluids and exudates, not to mention the lungs and pleuræ, in cases of pericarditis. In the cases mentioned the author described them as existing in exuberant growths on the aortic flaps in endocarditis. He obtained pure cultures of the bacillus from one case; in another the bacilli were associated with staphylococci. In one of the cases no disease of the lung could be demonstrated. Jehle further stated that these germs could make their way through the body not only in the lymph-channels, but also in the blood-vessels.

Epistaxis.—Bleeding from the nose used to be considered either a warning, a remedy, or a disease. The opinion that it is a disease is being more firmly established. F. C. Cobb (*Boston Med. and Surg. Jour.*, Jan. 4, 1900) thinks that it should really be called a symptom either of a lesion in the nose or of some general condition. The most common local cause is a deformity of the nasal septum. The deviation catches dust, this inflames the mucous membrane, and a scab is formed which is picked or scratched off, leaving an ulceration. Some time later this ulceration reaches a vessel and hemorrhage ensues. Fracture is very common among the local lesions causing epistaxis. Of all the constitutional diseases cited as general causes of epistaxis, Cobb has found nephritis to be the most common, and reports two cases. Epistaxis from this cause is usually severe, as the walls of the arteries are affected. Mild forms of epistaxis can be stopped by simple application of ice to the side of the nose, cold to the spine, or cold water injections. If hemorrhage is severe, a five to ten per cent. solution of cocain should be introduced on pledgets of cotton, and allowed to remain in for from five to ten minutes. If the bleeding does not cease, a ten per cent. solution of suprarenal capsule, made from tablets or powders, may be used. This acts magically but bleeding is apt to recur. If possible the bleeding point should be found and canterized with chromic acid or the galvanocautery, after cocainization. If necessary to plug the nostril it should be done by introducing strips of gauze along the floor of the nose with long forceps. The packing should remain in for from twenty-four to forty-eight hours and very carefully removed.

Therapy of Dionin.—The excellent work which has been done by von Mering in searching for

safe and efficient morphin succedanea has led to the discovery of a number of new synthetic remedies, the most recent of which, dionin, has been clinically examined by Th. Janisch (*Münch. Med. Woch.*, Dec. 19, 1899), especially with reference to its use in diseases of the respiratory organs accompanied by irritation and pain. The results have been highly gratifying. A number of cases of pulmonary phthisis are narrated in which dionin was successful in alleviating the cough, stopping the vomiting, diminishing the sweats and removing the insomnia without at the same time causing bad after-effects. The beneficial effects were no less startling in chronic bronchitis with emphysema. The author was thus stimulated to try the drug in the more acute affections, but noticed that here less uniform and prompt relief was obtained. His conclusions may be stated as follows: The sleeplessness is always remedied, although in cases in which large doses of morphin have been regularly administered previously, the drug often fails; mental dulness, nausea, and vomiting do not occur; diarrhea is often arrested, but constipation never results; expectoration is more free; the pains are ameliorated, and the night-sweats are less profuse. It is only in advanced cases of consumption, not necessarily complicated by laryngeal tuberculosis, that the irritation of the throat will demand the use of morphin. In asthma and allied conditions the employment of the latter drug, however, can be entirely dispensed with. Two or three daily doses of one-third of a grain or an evening dose of half a grain are recommended.

The same drug is discussed by Meltzer (*Münch. Med. Woch.*, Dec. 19, 1899) from the standpoint of the alienist. It had been previously shown that dionin possesses little superiority over morphin as a sedative in the various forms of insanity which are accompanied by severe excitement and emotional outbreak, but Meltzer is fully satisfied with the results he obtained in the mild hallucinations of females, especially in secondary dementia. The patients ceased to react to their morbid sensory disturbances, and in from a quarter to half an hour calm and quietude supervened. Excitement, such as occasionally occurs with hyoscine, did not appear, but as a soporific the drug seems to vary but little from morphin, it being not a true hypnotic but a sedative to the nervous system, causing this to react less readily toward external stimuli. Sequellæ, such as dulness of mind, palpitation, syncope, vomiting or increased excitement, have been experienced by the author in but three cases, and he recommends that the drug never be used when great excitement or irritability is present, or when the disease is of long duration or of great intensity. In comparing morphin with its various substitutes, the following may be said: (1) Morphin itself is characterized by many disagreeable sequelæ, and its continued use develops a dangerous tolerance. (2) Codein is generally less active, has similar after-effects, and its subcutaneous use is painful. On the other hand, it does not depress respiration, and therefore may be used with impunity in many cases in which morphin cannot be employed. (3) Peronin is not easily soluble, and has a disagreeable taste, but its administration is not followed by untoward symptoms. It is peculiar in that it irritates the capillary endothelia of the conjunctiva and increases the nutritive flow of lymph in the cornea, and thus may be employed as a subconjunctival injection. (4) Dionin also possesses this property; furthermore, its taste is not objectionable, it is freely soluble, does not depress the respiratory center, can be administered for a longer period without fear of tolerance, and its use is not followed by a train of unpleasant symptoms. (5) It is more sedative than its related drugs, and is especially good in mild hallucinatory and melancholic states.

Scrofula and Tuberculosis.—The ever-interesting etiology of scrofula is discussed by Rothholz, of Stettin (*Ther. Monatshft.*, Dec., 1899). He shows how frequently swelling of the lymph-node is associated with disease of the naso- and oropharynx and recognizes in these the cause in many cases. The various unhealthy conditions of ear, eye and face, which so often accompany scrofula in these cases, can be accounted for by extension or secondary infection from the nose. The acute or more chronic swellings seen after the exanthemata may also be due to a primary nasal focus. All these conditions disappear with proper treatment of the nose. That a true scrofulous lymphadenitis occurs cannot, however, be disputed. The presence of cheesy degeneration or of giant-cells without tubercle bacilli is not, however, sufficient to warrant a diagnosis. The latter are seen sparingly or not at all, but more positive results may follow inoculation of portions of the nodes or the use of tuberculin injections. Scrofulosis is thus generally regarded as a local tuberculosis of markedly chronic character. The infection may be descending, from the nose or tonsils often without directly involving these, or ascending, from the bronchial glands or lungs. We can never, however, be certain that the tuberculosis is the primary lesion, and it is the author's opinion that scrofula really is a chronic inflammation from unknown cause, which secondarily becomes infected by tubercle bacilli.

Hypertrophy of Prostate.—Having had a long experience with Bottini's operation for the relief of prostatic hypertrophy, R. and H. Rorig (*Central. für Krank. Harn- und Sexual Org.*, Dec., 16, 1899) are strongly convinced of its favorable influence. They advocate in every case a palliative treatment of several weeks' duration. If the result is not a satisfactory one, the prostate is cauterized through the urethra according to the method described by Bottini. The results of this treatment in their hands have been remarkably good, and the operation has the especial advantage of permitting the patient to go about after one or two days' rest. It is practically without danger.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

MEDICAL EDUCATION AND POLITICS.

THE question of higher medical education in New York State has passed successfully through the trying ordeals that have dogged its footsteps—the jealousies of rival institutions and the selfish interests of private corporations. No sooner, however, have the medical educational institutions of the State placed themselves in line with the advance guard of progress in medical education, established an abiding harmony between themselves and the State Board of Regents, and begun to feel the solid earth under their feet, than the entire educational structure is shaken by the proposed interference with its organization. The disinterested efforts of the Regents are now met by the blighting touch of politics. In the proposed unification of the educational system of the State the politicians have seen an opportunity to enlarge their sphere of spoils, and are attempting to degrade it to the ignoble service of party politics.

We publish to-day a letter from Dr. William H. Watson of Utica, in which he sounds a warning to the medical profession regarding the danger that threatens medical education in the State. Dr. Watson has for many years been Chairman of the Regents' Committee in Medical Education and he knows whereof he speaks. The placing of the power to appoint the Chancellor of the University in the hands of the Governor, at one stroke prostitutes the whole educational system to political uses. Every member of the profession throughout the State should protest to Senators and Assemblymen against this innovation. The present time-honored system has developed an educational department unsurpassed by any other State and productive of most satisfactory results. It was created by the unrivaled political genius of Alexander Hamilton and is now well advanced in its second century of fruitful existence. It is one of the very few institutions that have remained free from suspicion of corruption amid influences which in these later days tend to reduce everything pure, noble, and of good repute, if it can contribute to party power, to the debasing fluctuations and uncertainties of party politics.

Unify the system if it will make it more efficient, but keep it out of politics.

END-OF-THE CENTURY IDEAS OF GONORRHEA.

WE publish this week from the pen of Professor Neisser of Breslau, the well-known discoverer of the gonococcus, an article on the dangers to society from gonorrhea. Even to medical men some of the statements made by their distinguished German colleague will come in the nature of a revelation. Gonorrhea for generations has been considered scarcely more than a passing incident of youthful indiscretion, something that it was alloted to most of the male portion, at least, of the race to experience. Scarcely any more significance was attached to it than to one of the ordinary infectious diseases of childhood.

To consider the disease as a great popular plague, as Professor Neisser does, the universality of which is equalled only by that of measles, but the effects of which are of the most serious kind for the race in general—this is something new. And yet there is no exaggeration. The disease is unsexing large numbers of the population, men and women, every year. It is an important factor in the decrease of the birth-rate all over the world. It is the great causal element in the sterility of marriage, absolute and relative, or, as they call it abroad, one-child sterility. Finally, it is of serious import in the world's economy since it diminishes to a notable degree the wage-

earning capacity of its victims, not only during its acute manifestations but often for years.

All this Neisser has emphatically presented. His plea for greater publicity in the matter and for carefully devised instruction of the rising generation at the various seats of learning regarding the disease, should find a hearty response throughout the profession. This is a conviction that has found expression recently on more occasions than one in the editorial columns of the MEDICAL NEWS. No possible harm can come from the general dissemination of knowledge in this matter. On the contrary, it gives promises of great benefit to the race.

The second plea that, for the sake of the community in general as well as for the individual, hospital treatment should be conceded to patients suffering from venereal diseases whenever it is desired, is deserving of most serious consideration. The ethical priciples that dictated the establishment, in many of our hospitals, of regulations excluding such patients were founded on certain sentiments with regard to venereal diseases that are not shared by this generation. We have gotten beyond the notion that a man should be permitted to suffer the physical consequences of his transgressions of moral law. Moreover, it must be borne in mind that the penalty is apt to fall quite as severely on the innocent wife and children as on the evil-doer himself.

Professor Neisser's masterly review of a subject which his investigations have made him so competent to handle is calculated to do great good. And it is a source of gratification that the MEDICAL NEWS has been selected as the medium for the communication to the profession in America of Professor Neisser's ideas.

SCURVY, ITS PRESENT OCCURRENCE AND TREATMENT.

A CHANGE has come over medical sentiment during the past few years in regard to the frequency of scurvy. The cases that occur at the present time, however, do not present the easily recognizable conditions that made it impossible formerly to overlook or mistake the disease, *viz.*: the bleeding, spongy gums, the cutaneous hemorrhages, and the conspicuously faulty diet. On the contrary, they are frequently monosymptomatic, and the single symptom may be entirely distinct from those ordinarily set down in the text-books as characteristic of the disease.

The diagnostic points presented in the discussion of Dr. Carr's paper (see p. 51) by Drs. Jacobi and Koplik are of great practical importance and indicate that the possibility of scurvy must always be prominently before the practitioner's mind in dealing with obscure conditions that involve serious changes of metabolism.

The treatment of scurvy, fortunately, is most satisfactory. Meat-juice and milk are the ideal articles of diet, but in practise it has been found that, to achieve the best results, they must be supplemented by lemon- or orange-juice.

ECHOES AND NEWS.

NEW YORK.

$100,000 for Columbia.—Mr. John D. Rockefeller has presented $100,000 to Columbia University for the endowment of a Chair of Psychology.

Brooklyn Neurological Society.—At the annual meeting of the Brooklyn Society for Neurology, Dr. William Browning was elected President; Dr. R. C. F. Combes, Vice-President, and Dr. W. H. Haynes, Secretary, for the ensuing year.

Genito-Urinary Section.—At the last meeting of the Genito-Urinary Section of the Academy of Medicine, Dr. W. K. Otis was elected Chairman for the ensuing year. The date of meeting was also changed from the second Tuesday to the third Wednesday in the month.

An Electric Ambulance.—St. Vincent's Hospital has a horseless ambulance which is operated by an electric motor supplied with power from a storage battery. It is the gift of Edward Kelly, Esq. Its cost is $3000, and it can travel at the rate of ten miles an hour. It is in many respects similar to the present city ambulances, but it is equipped in front with sliding, glass doors for use in stormy weather.

New York Neurological Society.—At the annual meeting of the New York Neurological Society the following officers were elected for the year 1900: President, Frederick Peterson, M.D.; First Vice-President, Joseph Collins, M.D.; Second Vice-President, L. Stieglitz, M.D.; Recording Secretary, Pearce Bailey, M.D.; Corresponding Secretary, Lewis A. Conner, M.D.; Treasurer, Graeme M. Hammond, M.D.

The Babies' Hospital.—The Rev. Dr. Charles Cuthbert Hall, in an address, declared that the Babies' Hospital has set an example for the care of the very young which has been followed in a large number of cities. This hospital sends pamphlets to poor people explaining the proper care of a child. During the past year 394 patients were treated. Thirty-four nurses have been trained and graduated in the training school which the hospital conducts.

Montefiore-Home Work.—The fifteenth annual

report of the directors of the Montefiore Home for Chronic Invalids shows that during the last year 609 patients were treated; 194 were discharged, of whom 114 were improved and 36 were cured. The average death-rate was 16.91 per cent. There are 132 cases waiting to be received. Only 39.19 per cent. of the applications received during the year could be accommodated with the present facilities. A sanitarium is being built, at Bedford Station, Westchester County, to which all of the patients afflicted with pulmonary diseases will be removed.

Widows and Orphans.—The New York Society for the Relief of Widows and Orphans of Medical Men has issued its fifty-eighth annual statement, 1899. Its funds now amount to $234,981.86, securely invested, and its income for 1898-9 was $10,301.59. Under the present by-laws of the Society the annuities allowed are: To the widow of a member an annuity of $400 a year, but for every ten dollars or multiple of ten of income an amount equal to fifty per cent. of said income shall be deducted from the annuity. Each child entitled to relief is allowed $100 per annum, subject to the same conditions as a widow. The Society has extended aid to eighteen widows and six children of deceased members during the past year.

"Archives of Neurology and Psychopathology."—Although somewhat belated this number of Volume II. of *The Archives,* coming from the Pathological Institute of the State Commission in Lunacy, shows that the promises of the editors are commencing to be realized. The present number contains two short and practical chemical papers by Dr. P. A. Levene on the proteids of the brain and the iodide compounds found in the body following the administration of potassium iodide, and a monographic treatment, which is a masterpiece of work in every way, by C. J. Herrick on the cranial nerve components of one of the bony fishes. This study received the prize of the Alumni Association of the College of Physicians and Surgeons. It is an invaluable contribution to those interested in comparative neurology.

The Suicides of 1899.—During 1899 *The* (New York) *Sun* reported 569 suicides in this city, of whom 442, or 78 per cent., were males. Of the whole number 226 shot themselves, 141 took poison, 43 died by hanging, 54 by gas, 37 by drowning, 30 by cuts or stabs, 22 by leaps and 9 by other methods. In 7 cases the method was not stated. Shooting was more popular with men and poisoning with women. Hanging was slightly more frequent among the males proportionately to their respective numbers. Twenty-four of the 30 who died by cuts and stabs cut their throats. In 16 instances the razor was used. The poison most frequently used was carbolic acid, which was taken by 54 per cent. among the males and 75 per cent. among the females who took poison. Of the total female suicides 37.8 per cent took carbolic acid. The stated causes of 267 of the 569 suicides were: Out of work 39, love episodes 18, domestic afflictions 54, sickness 57, business troubles 39, crime 23, other causes 37. Some absurd reasons for self-destruction were: A leaky roof; failure to get to a Christmas dinner, and the threat of a bath.

The City's Charities.—In their twenty-seventh annual report to the State Charities Aid Association, the New York County Visiting Committee complimented Commissioner John W. Keller upon the marked improvement during the past year in the condition and management of the various institutions in the Department of Charities of New York City. As much as possible has been done with the limited appropriation of $200,000. An earnest desire to improve the condition of the public institutions has been evident. There is a gratifying decrease in the number of inmates during the year as probably indicative of better industrial conditions in the community and also of more careful discrimination in the admission of inmates. Paid employees have been substituted for prison labor—a very commendable improvement. Many other improvements are needed, notably a new building for the Harlem Hospital. It is stated that in view of the excellence of the maternity service in the city institutions, it is not proper that the city should pay large sums of money to private institutions for the care of such cases when the city's own institutions are able to receive them and to provide for them at much less cost. The special committee of the State Charities Aid Association appointed to consider the subject of public aid to private institutions has reported to that body its conviction that the plan of granting public subsidies to private institutions has inherent and grave dangers which cannot be obviated and that no plan can be devised which will insure wholly satisfactory results. The city authorities, who have practically complete control in the matter, should begin at once to reduce the amount so appropriated with a view to finally discontinuing absolutely the custom in the near future.

PHILADELPHIA.

The Obstetrical Society.—The election of officers for the current year by this Society was held during the past week, the results being as follows: President, Dr. John C. Da Costa; vice-presidents, Drs. John M. Fisher and George M. Boyd; secretary, Dr. Frank W. Talley; treasurer, Dr. John G. Clarke.

The College of Physicians.—The annual election of officers of the College of Physicians which was held last week resulted as follows: President, Dr. W. W. Keen; vice-president, Dr. H. C. Wood; censors, Drs. Alfred Stillé, William F. Norris, Richard A. Cleeman, Arthur V. Meigs; treasurer, Dr. Richard H. Harte; honorary librarian, Dr. F. P. Henry.

New Children's Ward.—At the last meeting of the Board of Managers of the Episcopal Hos-

pital, held last week, it was decided to shortly begin the erection of the new Aspinwall Ward for Children, the fund for this purpose, bequeathed several years ago by the late Anna R. Aspinwall of Pittsburg, being now in possession of this institution. The cost of this addition to the hospital will amount to $200,000.

School Medical Inspectors.—In compliance with the agreement reached a few weeks ago by the Board of Health and the Board of Education, this week saw the beginning of the system of daily medical inspection of the public school children, by the corps of volunteer medical inspectors recently appointed by the city on the recommendation of the various medical schools and hospitals. Thus far 210 physicians have been appointed to conduct these inspections, the present system being regarded as experimental, to become permanent later, with a paid corps, if it proves satisfactory.

State Board of Medical Examiners.—The results of the midwinter meeting of this Board, just concluded, have been embodied in a report which will be filed at Harrisburg and will form the subject for action at the meeting to be held at the Capital this week, by the State Medical Council. On account of the recent and evidently sustained charges of fraud in the State Medical examinations, this report is awaited with especial interest, and it is promised that the current meeting of the Council will develop a number of startling revelations in reference to this unsavory and decidedly well-advertised episode which involved in its meshes not a few of last year's graduates.

Palladium Chloride in Phthisis.—At the last meeting of the Philadelphia County Medical Society, held January 3d, Dr. S. Solis Cohen related his experience with this palladium salt in the treatment of pulmonary tuberculosis, his attention first being drawn to the drug by John Johnson, a nurse in the Jefferson Hospital, who had for a long time used it for the preparation of ligature material because of its marked antiseptic and oxidizing properties. The drug was given in solution, made with the aid of hydrochloric acid, and should be used in the strength of 15 grains to the fluid ounce. The initial dose is 5 drops of this solution, well diluted with water, and administered from ten minutes to one-half hour before meals; the dose is later doubled, if the patient stands it well. The only untoward effect noticed from its administration was an acceleration of the cardiac action, the fact that this was due to the drug being shown by the subsidence of this symptom when the drug was withheld, and its reappearance as soon as its readministration began. The action of palladium chloride in pulmonary tuberculosis is thought to improve nutrition, and to lessen the activity of septic processes. In some cases it gives better results, if alternated with iodoform for several days at a time. Dr. Cohen is inclined to regard the drug as of real value in the treatment of phthisis, many cases improving in weight and losing febrile manifestations from its use. A number of cases, some detailed, were quoted to demonstrate its usefulness in the treatment of this condition.

Rupture of the Liver.—Dr. Joseph Sailer, at the last meeting of the Pathological Society of Philadelphia, held December 28th, reported an interesting instance of this kind. The patient, a man who died five days after having been violently thrown down and trampled on in a crowd, had received a severe blow in the region of the liver, with no external evidences of the injury with the exception of a trifling contusion with more or less abrasion at the seat of the injury. Autopsy showed that the peritoneal cavity was filled with blood, but that no inflammation of the peritoneum existed, this membrane appearing normal after a brownish-red deposit was wiped away. An enormous laceration of the liver was found, extending in the form of a slit through almost the entire thickness of the right lobe. The primary point of rupture seemed to lie deep in the substance of the organ, from which situation a number of irregularly shaped fissures radiated in various directions, producing extensive lacerations in many parts of the liver-substance. Fan-shaped areas of necrosis surrounded these lacerated portions of the organ. The most interesting point in the case appeared to be the fact that death had not been due directly to the rupture of the liver or to the extensive peritoneal effusion of blood, for cultures made from the blood showed the presence of an organism corresponding to the pneumobacillus of Friedländer. A white mouse inoculated with the growth died the following night, and growths made from the tissues of this animal were characteristic of the organism in question. The speaker thought it probable that the pneumobacillus had gained access to the liver through the bile-ducts and, by means of the rupture, entered the abdominal cavity, and in the blood there present had developed its toxins. The therapeutic question in this case seems whether or not it is advisable to evacuate the abdominal cavity in such cases when the symptoms of peritonitis are present.

GENERAL.

Dr. Conan Doyle has volunteered his services to the British army for service in South Africa, and will go out with the Langman field hospital.

Marine Hospital for Honolulu.—The President issued an order on January 6th setting apart about seven acres out of the government reservation, east of the "Punch Bowl," in the Island of Oahu, Hawaii, as a site for a United States Marine Hospital for the Port of Honolulu.

Influenza Epidemic.—It is reported from London that the weather there is most debilitating and dreary. Influenza has become epidemic again, and there is sickness, as well as mourning for the heroes of the war, in nearly every West End house.

Dr. Czerny Coming.—By invitation of Dr. R. F. Weir, the President of the American Surgical Association, Professor Czerny, Professor of Surgery at Heidelberg, has arranged to be present at the next meeting of the Association, at Washington, in May. He will read a paper upon surgical operations for the relief of gall-stones.

The Association Medal.—At the meeting of the American Medical Association, held June 4, 1897, it was resolved to restore the former policy of the Association in favor of offering annually a gold medal for meritorious scientific work. The committee for this year consists of Drs. George M. Gould of Philadelphia, E. Fletcher Ingals of Chicago, and T. W. Huntington of Sacramento, Cal. For information governing the competition apply to committee.

$5,000,000 to Charity.—By the will of the late Robert Breck Brigham, a hotelkeeper of Boston, the bulk of an estate of $5,000,000 is given to charity. The chief provision is for the establishment of a new hospital in Boston to be known as "The Robert B. Brigham Hospital for Incurables," which is to be maintained as an institute for the support and treatment of such Boston people as are unable to support themselves by reason of incurable disease or permanent physical disabilities.

Dr. Schenck Removed.—As the result of a demand by the Vienna Medical Faculty that Dr. Schenck be dismissed for the alleged "frivolous publication of scientific matter," he has received permission from the Minister of the Interior to retire on a pension. Dr. Schenck was professor at the University of Vienna and President of the Embryological Institute. This severe discipline has been administered on account of the publication of his book, in which he asserted that he had discovered the power of predetermining the sex of offspring. It savored too much of personal advertising.

Another Old School Doctor has appeared in fiction, this time in a book by Stacpoole. When on earth the doctor was much beloved by the people of a remote part of Somersetshire, whom he ruled as well as healed. His characteristic gruffness is well illustrated in his opinion of the germ theory. "Damn microbes; there ain't any such things. I remember the time when *The Lancet* was a paper that a man could understand. That was when Watson was alive and Jenner and Gull were young men. Now it's all packed full of microbes and antiseptic surgery. Microbes there may be in London, but there ain't any in Somerset."

Barbarians?—For those of us who cling to the Greek notion that all are barbarians who speak another tongue, it is well to notice the titles of the articles in a little volume published by the Ekaterinoslav Medical Society to commemorate the twenty-fifth anniversary of its foundation. "The Comparative Value of Disinfectants," "Hypnotism as a Therapeutic Means," "Railway Ambulance Cars," "Syphilis of the Heart," and "The Sanitary Condition of Jewish Primary Schools," are some of the subjects considered, which show that Southern Russia may be a long way removed from New York, London and Paris in miles, but is not so far away in years.

Mosquitoes and Japanese Literature.—A correspondent of the *Lancet* points out that in a little Japanese romance, published in 1885, the following statement occurs: "The Japanese declare that its (the mosquito's) constant attacks bring on a kind of fever; and this is by no means improbable, having in view the fact that this pest prepares for the summer campaign by a course of training on the swamps and marshes of the neighborhood, and inoculates whole families with the essences of these odoriferous hunting-grounds. If sleepless nights combined with repeated doses of this subtle poison were not to give rise to feverish symptoms, it would, indeed, be strange." Truly there is nothing new under the sun.

Gynecology in Guam.—Captain Leary, the Governor of the Island of Guam, has recently forwarded to Washington what is considered a remarkable innovation in naval requirements—a requisition for a full set of obstetrical and gynecological instruments. It appears that the naval surgeons who are stationed at Guam have been very active in establishing hospitals in several of the larger villages; one contains ten beds and another as many as twenty. The surgeons have been disseminating among the people much needed knowledge of the rudiments of hygiene and the care of the sick. From the requisition above referred to it is evident that the female population of the Island are about to be initiated into the most recently approved scientific surgery.

Information Wanted.—The psychophysiology of anesthesia is a productive subject greatly in need of adequate investigation and discussion. Both pure science and practical surgery have doubtless much to gain from a more extensive study of experiences under ether, chloroform, nitrous oxide, etc., than has yet been made. Scientific literature has frequently contained reports of single cases, made chiefly because of their strangeness, but what is now desired is a very large number of accounts of the ordinary experiences as they "run." Printed blanks have been prepared on which replies to certain simple questions may be written. All persons, and especially hospital surgeons, officers of medical societies, and instructors in medical schools, are respectfully requested to send to the undersigned for as many of these as they care to distribute among individuals who have been under an anesthetic within a period not too long to prevent accurate recall of the facts. The blanks will be gratefully sent (and received when filled out) by George V. N. Dearborn, M.D., Physiological Laboratory, Harvard Medical School, Boston, Mass.

Housing Members at the Congress.—The secre-

tary-general of the International Medical Congress has issued a notice saying that the Paris executive has been considering the important question of housing foreign members who attend the congress. The rector of the Academy of Paris will place at the disposal of the General Committee 800 beds in the various lycées at Paris during the congress week, and it is hoped that an additional 200 may be obtained, making a total of 1000. The price of each bed is fixed at five francs fifty centimes a day, $1.10, to comprise bed, attendance, and the eight o'clock "petit déjeûner." The beds are in dormitories, and not in separate rooms. Nothing is yet decided about the distribution of these beds. The chief Parisian excursion agents are now ready to receive applications for rooms from intending visitors who do not patronise Messrs. Cook & Son, the agents recommended by the English committee. The names of the French agencies are (1) "Voyages Duchemin," 20 Rue de Grammont, Paris; (2) "Voyages Modernes," Rue de l'Echelle, No. 1, Paris; (3) "Voyages Pratiques," 9 Rue de Rome, Paris; (4) "Agence Desroches," 21 Rue de Faubourg Montmartre, Paris; (5) "Agence Lubin," 36 Boulevard Haussmann, Paris.

Program of the Congress.—The program of the Congress of American Physicians and Surgeons, to be held at Washington, D. C., May 1, 2 and 3, 1900, is as follows: There will be a general session in the afternoon of Tuesday and of Wednesday.

Tuesday.—Papers will be read as follows: Prof. Theobald Smith of Boston, "Adaptation of Pathogenic Bacteria to Different Species of Animals;" Dr. Samuel J. Meltzer, of New York, "The Physiological Resources of the Body in Its Defense against Bacteria and Their Toxic Products;" Prof. Harold C. Ernst, of Boston, "Flagella and Serum Reactions;" Dr. Richard C. Cabot, of Boston, "Relation of Bacteriology to Clinical Medicine;" Dr. Edward R. Baldwin, of Saranac, New York, "Bacterio-Therapeutics with Especial Reference to Tuberculosis;" Prof. William S. Thayer, of Baltimore, "The Aetiology of Malarial Fevers;" Prof. George Dock, of Ann Arbor, Mich., "Infection by Animal Parasites;" Prof. Simon Flexner, of Philadelphia, "Bacteriology of Dysentery."

Wednesday.—Prof. William Osler, M.D., LL.D., of Baltimore, "Modern Therapeutics;" Dr. Clarence J. Blake, of Boston, "Sociological Status of the Physician;" Poem by Dr. S. Weir Mitchell, M.D., LL.D., of Philadelphia, "The Evolution of the Physician." 8 P. M., address by the President of the Congress, Prof. Henry P. Bowditch, M.D., LL.D., D.Sc., "The Medical School of the Future," to be followed by a reception.

Thursday.—8 P. M., banquet of the members of the Congress.

The Plague at Manila.—We noted last week that the plague was reported at Honolulu. This news has been confirmed. This week comes the official announcement that plague has broken out among the natives at Manila. Its occurrence, however, is not looked upon with alarm. It has been expected for some time. The strictest quarantine will be enforced with regard to vessels coming from that port, and the Marine Hospital Service already has a party of experts on the ground and more en route to take charge of the city. Surgeon-General Sternberg gives the positive assurance that Colonel Greenleaf, the Assistant Surgeon-General and Chief Surgeon of the United States army in the Philippines, is exceptionally well fitted to cope with the present emergency. He has all the resources needed at his command and there is no doubt that the disease will soon be stamped out. So far, in the East the disease has practically always been confined to the native population. This is notably true of Hongkong, where it has existed for many months, without causing any considerable fatality among the European population. It was probably from Hongkong that the disease found its way to Manila. The medical officers at all times have been on the watch to prevent this, but owing to the short distance from Hongkong to Manila, and the large amount of traffic carried on in a small way by native junks and dhows, the ultimate introduction of the disease into Manila was inevitable. Up to the middle of the week six cases and four deaths had been reported there. The disease was sporadic in various places, not epidemic at a single point.

Reciprocity of State License.—The following resolution was adopted by the Illinois State Board of Health, October 10, 1899: Resolved: That applicants for a State certificate to practise medicine and surgery in the State of Illinois, who have been examined and licensed by other State Examining Boards maintaining standards not lower than those provided for in the Act to regulate the Practise of Medicine in the State of Illinoise, in force July 1, 1899, shall be granted certificates without further examination, on payment of the fees required by the Act, providing that the applicant, who must be a graduate of a medical college in good standing with this Board, shall present with his license an affidavit from the president or secretary of the State Examining Board showing that the requirements of said examining board at the time of his examination were equal to those exacted by this Board under the present law, and providing, further, that the said State Examining Board will grant licenses without examination to applicants holding certificates issued by the Illinois State Board of Health under the act now in force.

Note.—Under the provisions of the Act to Regulate the Practise of Medicine in the State of Illinois in force July 1, 1899, an applicant for a certificate to practise medicine and surgery in the State must present evidence of being a graduate of a medical college in good standing as may be determined by the Board, and must pass an examination in those general subjects and topics,

a knowledge of which is commonly and generally required of candidates for the degree of doctor of medicine by reputable medical colleges in the United States. No medical college will be considered in good standing after January 1, 1900, which does not require of all graduates receiving diplomas after that date, as a condition of graduation, an attendance upon four full courses of lectures in four separate years.

Medical News from Seat of War.—Sir William MacCormac and Mr. Frederic Treves are finding abundant occupation in South Africa from the sad results of the past two or three battles. No less than four train-loads of wounded have been brought into Maritzburg to the hospital from the battle of Colenso alone. Mr. Treves is operating incessantly and Sir Willim MacCormac superintending the collection and transfer of the wounded. An interesting illustration of the fact that it is bacteria rather than bullets which the soldier has to dread among the risks of war was given this week in the return of one of the sick transports. Out of a total of some hundred and thirty invalided officers and men, less than one-third were suffering from the results of battle-wounds. This minority, however, included *all* the officers, among whom the battle-mortality has been something terrible, as the "traditions of the British army" most stupidly forbid their taking cover or even lying down, and the Boer marksmen make a special point of picking them off. Now, however, common sense has triumphed and they are not only ordered to take any reasonable advantage of cover and lie down with their men, instead of marching up and down in front of them as hitherto, but to dress in khaki without a sign of ornament and carry a rifle instead of the foolish and useless sword, which simply served to attract the enemy's fire.

Almost every returning transport brings its wan but plucky and cheerful burden of sick and wounded, who are promptly distributed among the various military hospitals, Netley receiving the lion's share. Offers of accommodation from homes and hospitals continue to come in almost daily, one of the latest being from Devonshire in the West, but so far the army establishments have been found adequate to the demands.

A new service-rank has been proposed for the Army Medical Corps, that of "doctor's messenger." A plucky and enterprising Australian youth of ten has suggested it and created quite a furor by volunteering to accompany the next regiment from Melbourne in that capacity. And no doubt a handy boy could be of great service in fetching and carrying for the surgeon in his improvised field operating-room, when perhaps a grown man could hardly be spared from bearer-service. So long as infants of from ten to fourteen years are allowed to accompany the troops in the field and run into battle, as drummers, buglers, etc., there seems no reason why similar Lilliputians should not be enlisted upon the life-saving side of the force. Some doctor's messenger may one day gloriously eclipse the unhappy record of little Bugler Shurley, who "cried to be taken into battle," and then shot three Boers with his own revolver. One life saved would beat this 1000 per cent.

Sir William Thompson, K. B., late President of the Royal College of Surgeons, has been appointed chief surgeon to the English forces in South Africa. Major Baly and forty-one men of the British Medical Corps, who were left at Dundee when their fellows evacuated the town, were released by the Boers and were permitted to proceed to Delagoa Bay.

OBITUARY.

WILLIAM A. HAMMOND, M. D.

William A. Hammond, M.D., ex-Surgeon-General of the United States army, died at his residence, in Washington, at 9 p. m., Friday, January 5th, having been stricken with heart failure after the hurried ascent of a flight of stairs; death came almost immediately. Dr. Hammond was born at Annapolis, Md., August 28, 1828. He was graduated at the Medical Department of the University of the City of New York, and entered the United States army in 1849 as an Assistant Surgeon, with the rank of First Lieutenant. In October, 1860, he resigned to accept the professorship of anatomy and physiology in the University of Maryland. At the beginning of the Civil War he again entered the army, and was assigned to the organization of general hospitals in Hagerstown, Frederick and Baltimore. Afterward the Sanitary Commission urged his appointment as Surgeon-General of the army, and in April, 1862, he received this commission with the rank of Brigadier-General. He instituted radical changes in the organization of his department and managed his official business with great ability. With keen appreciation of the wonderful opportunities for instructive and unusual specimens of gun-shot injury he established the Army Medical Museum at Washington, and suggested the plan of the Medical and Surgical History of the Rebellion. Unfortunately his career was abruptly closed and his reputation clouded by a charge of irregularity in the award of contracts for medical supplies. He was tried by court-martial and dismissed from the army August, 1864. He then removed to New York, where he practised his profession, making a specialty of diseases of the nervous system, and promptly established himself as a recognized authority. He was professor of diseases of the mind and nervous system successively in Bellevue Hospital Medical College and in the Medical Department of the University of the City of New York. Later he joined with others of his colleagues in founding the New York Post-Graduate Medical School.

In accordance with an act of Congress, which was passed in 1878, the President of the United States was authorized to review the proceedings

of the court-martial. As a result of the President's investigation Dr. Hammond, in August, 1879, was exonerated and restored to his place on the rolls of the army as Surgeon-General and a Brigadier-General on the retired list.

Dr. Hammond was a voluminous writer upon subjects connected with his specialty and contributed frequently to current medical literature. He founded and edited the *Maryland and Virginia Medical Journal,* and was one of the organizers of the *New York Medical Journal.* He established and edited for a time the *Quarterly Journal of Psychological Medicine and Medical Jurisprudence.* Dr. Hammond was a man of commanding presence, and possessed of extreme self-confidence and remarkable personal magnetism.

Two children survive him, Dr. Graeme Monroe Hammond of New York, and the Marchioness of Lanza, formerly Miss Clara Hammond. His remains were interred at Arlington Cemetery with full military honors.

CORRESPONDENCE

THE MEDICAL PROFESSION AND THE PROPOSED CHANGES IN THE NEW YORK STATE UNIVERSITY.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—At the time of the creation of Boards of Medical Examiners in this State, in 1890, it was found difficult to determine the proper and most fitting place in which to lodge the authority requisite for their administration. After long discussion, during which various plans were suggested, as, for instance, having the members of the Boards appointed by the Governor, by the Board of Health, etc., none of which were satisfactory, it was decided to lodge that power in the Board of Regents, for the reason that it was the only place in which the power of appointment could be located without danger that medical education might become the spoils of partisan politics. The original constitution, mode of election and life tenure of the members of that Board were such that it would necessarily be absolutely non-partisan and impartial. That this must be so was a self-evident fact.

(1) Because it comprised within its membership Presbyterians, Methodists, Unitarians, Quakers, Episcopalians, Roman Catholics, Baptists, and men of no religious belief—in a word, it was a Board from which no man, possessing good character and suitable educational attainments, could be excluded on account of any peculiarity of belief.

(2) This safeguard was reinforced by the fact that its members, having been elected for life or good behavior, would be under no necessity of looking for re-election, and hence that class of temptations which beset the members of any board chosen for only a brief term of years would not appeal to the members of this Board.

(3) Moreover, at that time the Board of Regents had already been in existence for ninety-six years and no charge of partiality, partisanship or sectarianism had ever been alleged against it. This is one of its most estimable features. In the language of a former Chancellor, the late George William Curtis, "the highest tribute to the Board of Regents is the *truth* that although every member is necessarily elected by a party vote, yet at the door of their council chamber, party vanishes and politics disappear." It is a department of the State from which all political, personal and sectarian influences have been entirely eliminated. All its deliberations are conducted in the spirit of the Virgillian motto, "Tros Tyriusque mihi nullo discrimine agetur."

The writer can testify that every case which has arisen in the course of the eighteen years during which he has been a member and a regular attendant upon its meetings, has been decided solely upon its merits. The Board of Regents is, therefore, a central, educational and administrative body, which is at the same time an impartial court (the exact analogue of which exists in no other State) to pass upon the preliminary requirements for medical education, and to supervise and conduct the examinations for medical licenses to practise. It may be here said, in passing, that an attempt is at this time being made in other States to adopt the New York Medical Law. It has failed in several cases for the reason that in those States there is no similarly constituted body in which to lodge the authority for their construction and supervision. There are Boards of Regents, it is true, in several of our sister States, but they are elected for comparatively brief terms of office, and from want of permanence of tenure do not have the same independence which has always characterized this Board, whose members, fortified by years of experience, have devoted themselves to unrewarded public service, with no compensation save the consciousness of having to the best of their abilities performed their duty to the commonwealth. It is now an honorary life office, without pecuniary compensation of any kind, except the reimbursement of the necessary traveling expenses of its members, and as such has commanded the services of men of the highest character in the State. It requires both time and experience to become familiar with its multiplied and varying duties, and it would not be worth while to attempt it for a brief term of years without compensation.

The changes which have been proposed by four of the seven Unification Commissioners cannot but be mischievous. These gentlemen advocate the appointment of the first Chancellor of the proposed Department of Education by the Governor with the consent of the Senate, to which arrangement the other three members of the Commission are opposed.

While no one has a more exalted estimate of the character, independence and courage of his convictions, of the present occupant of the guber-

natorial chair of this State than has the writer, yet, should the plan urged by the majority of the Commission go into effect and the appointment of a Chancellor devolve upon his Excellency, Theodore Roosevelt, it would still be very unfortunate for the reason that such an example having been once established, other Governors might use the power for purely political purposes. Says the *New York Tribune* in an able editorial article, January 6th, "It is safe to predict that a political power affecting twelve thousand common schools, more than thirty thousand teachers, and nearly every family in the State, if it were once lodged with the Governor and Senate, would never be surrendered by the politicians to a non-partisan body beyond their reach. Mr. Melvil Dewey from an experience of eleven years, in a letter to the Governor in which he opposes other features of the report, uses the following emphatic language: "There is another consideration at least tenfold more important than this unification and that is that education in this State should be kept absolutely free from the domination or interference of partisan politics." And again, "I am forced to believe after mature deliberation that the danger of injury to our educational interests, if their plan should be adopted without material modification, is vastly greater than any possible good that may come from the improvement suggested."

The existing mode of constitution and tenure of office of the Regents has worked admirably for 115 years. The life tenure puts its members beyond political control, and, as has been well said by another: "The fact that the members are beyond political control discourages political manipulators from seeking to elect as regents the kind of men who are submissive to political control, and has thus placed upon the Board men whose motives have always been above suspicion."

That there is great danger of lowering the standard of medical education from any radical change in the constitution or life tenure of the Board is evident. This Board has administered the system of medical examinations which has done so much to elevate the character and standing of the profession in this State, and which by scholars and publicists is conceded to be the most perfect in the world, with an independence and impartiality which can be expected only from a board constituted as this has been. Its supervision of the ascertainment of the qualifications of members of the medical profession meets with the approval of the educated members of the profession everywhere and of all schools of medical belief. Why, then, should it be changed? I am unwilling to believe that the Legislature will consent to it, and I trust that the thinking men of our profession will urge upon their representatives in that body the wisdom of standing by the existing system as it has been handed down to us by the fathers of the State.

Wm. H. Watson, M.D.

Utica, New York, January 8, 1900.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, January 1, 1900.

DEATH OF SIR RICHARD THORNE—LONDON HOSPITAL FUNDS—LEAGUE OF MERCY—SCHOOL ATTENDANCE—DIPHTHERIA IN GIRLS—PROF. U. C. TIRARD'S APPOINTMENT—BORACIC ACID AGAIN AS A FOOD PRESERVATIVE.

THE death of Sir Richard Thorne comes as a grievous surprise to the profession, as it was only a few days ago that he was taking a most active part in the warm debates of the General Medical Council. Although a prominent figure in sanitary and medical circles for thirty years past his age was only fifty-eight so that years of usefulness in his high position as principal medical officer to the Local Government Board were yet expected of him. Sir Richard was a St. Bartholomew's Hospital man and a graduate of the University of London. At thirty years of age he was appointed a medical inspector to the Privy Council, and ever since then has been prominent in matters connected with the public health. He has been official delegate to most of the great international sanitary conferences and a prominent member of the Royal Commissions upon Tuberculosis and Sewage Disposal, a Fellow of the Royal Society, a Fellow of the Royal College of Physicians, lecturer and examiner in Public Health to the Universities of Oxford and Cambridge, and to St. Bartholomew's Hospital; honors crowded upon him until he was knighted in 1897.

His contributions to medical literature consisted of papers upon "The Origin of Infection," "The Progress of Preventive Medicine During the Victorian Era," "The Natural History and Prevention of Diphtheria," and what attracted the widest attention of all, the Harleian lectures of last year upon the "Prevention of Tuberculosis." These admirable addresses stirred the popular mind in an extraordinary manner and had much to do with stimulating the agitation, resulting in the formation of the National Association for the Prevention of Consumption. His graphic statements as to the spread of tuberculosis through diseased milk, and the alleged increase of tabes mesentrica in children as connected with the wider use of milk as an infant-food, attracted special attention.

The report rendered at the annual meeting of the Metropolitan Hospital Sunday Fund showed that the total collections of the past year aggregated nearly $270,000, an increase of $65,000 over the previous year. If the Prince of Wales Fund can manage to equal this, the regular annual deficiency between income and expenditure of the great city hospitals, estimated as at least $100,000, will be practically made good.

In not very favorable contrast to this record of growth, comes the preliminary report of that delicately-perfumed and highly aristocratic organization, the League of Mercy, organized nearly a year ago. It will be remembered that

this was a most select scheme of hospital fund-collecting organization, headed by the Prince of Wales and officered by half the titled personages of England, each of whom was to have the power of appointing committees of plebeians, every member of which was to make herself responsible for the collection of a certain sum to be extorted from her suffering friends. We described it at the time as a sort of charitable "snowball-scheme" under aristocratic patronage and gravely doubted its wisdom and prospects of success. The outcome, so far, seems to have justified the position, for it was announced to the meeting that although 883 vice-presidents and lady vice-presidents had been nominated and eighty-two branches organized, the net outcome of nine months' polite activity had reached barely $22,000, and of this only $5000 had so far been forwarded to the Hospital Fund. So that the society lady, *pur sang*, as a charity-collector does not seem the success which had been expected. After all it is your self-made man who parts with his money most generously and freely, and the noble collectors may have worked too exclusively in their own set.

Prof. W. R. Smith, medical officer to the London School Board, in the second of his Harleian lectures upon diphtheria this week, dealt chiefly with school attendance as a factor in the spread of the disease. From the careful study and comparison of a large number of statistics, American and Continental, as well as English, he is inclined to the consoling conclusion that school-attendance is a comparatively unimportant factor in the spread of the disease, and that the chances of communication through the play of children upon the street and in each others' homes, are rather increased by closing the schools, and constitute almost as great a danger.

He called attention to the serious increase with age of liability to the disease in girls as compared with boys, growing from a slightly lesser mortality during the first year to an equal one in the third year and reaching an excess of thirty per cent. between the fifth and tenth years. The careful comparison of the different influences surrounding boys and girls during these school years has failed to account for this marked variation of liability and fatality.

Prof. U. C. Tirard has been appointed to the Chair of Medicine in Kings College, vacant by the resignation of Prof. L. Burney Yeo.

A writ of attachment has been issued by the Queen's Bench against all the Leicester Board of Guardians as a result of their first delay, and their evasive pretence at appointing a vaccination-officer. The writ gives opening until the fifth day of the next sitting for the Guardians to make a genuine compliance.

Another of the unfortunate differences of medical expert opinion which are so lamentably common, has occurred before the Committee on Food Preservatives this week *in re* boric acid. The use of this was condemned upon the sound and well-known grounds so often presented by Prof. Boyce and Dr. Amsett, of University College, Liverpool, but Dr. Robert Bell, of Glasgow, actually took up the cudgels vigorously in its defence, alleging that it was less harmful than either salt or saltpeter, was invaluable in surgery, had saved many lives by its prolonged use as an antiseptic, etc., etc. All these statements are, of course, true enough, but they have nothing to do with the question at issue. Salt and saltpeter are self-limiting as to the proportion in which they can be used on account of their taste, while boracic acid may be present in considerable quantities without detection. Hence the man who buys over-salt butter knows just what he is doing, while he who buys borated milk does not, and this is precisely the point in discussion, one of selling under false pretenses.

INFLAMMATION OF THE ETHMOIDAL CELLS—INADEQUACY OF POLICE REGULATIONS TO CONTROL THE SPREAD OF SYPHILIS—IMPROVEMENTS IN THE TECHNIC OF GASTRO-ENTEROSTOMY — VARIATIONS OF TEMPERATURE DUE TO HEMORRHAGE—OPERATIVE AND NON-OPERATIVE TREATMENT OF COXALGIA—UNUNITED FRACTURES CURED BY THYROID GLAND—CURE OF THE MORPHIN HABIT—DEATH FROM CALOMEL—KERNIG'S SIGN PRODUCED BY MENINGEAL HEMORRHAGE—IPECAC TO CONTROL HEMORRHAGE—ANESTHESIA PRODUCED BY INJECTION OF COCAIN INTO THE LUMBAR CORD.

At the Academy of Medicine in Paris, November 7th, Koenig called attention to an inflammation of the ethmoidal cells characterized by a hyperplastic periostitis, always situated in the upper and internal portion of the orbit. After the usual symptoms of an acute coryza, a little non-fluctuating tumor, painful on pressure, appears in the inner angle of the orbit. It is accompanied by a slight edema of the eyelids. The acute symptoms subside in a few days and leave the periosteal tumor. If one cuts into it only blood will be obtained. The prognosis is a favorable one for, unlike empyema of the ethmoidal cells, the process tends naturally toward recovery.

At the session of November 14th, Fournier admitted the entire inadequacy of police regulations to control the spread of syphilis. The only prophylactic measure which is of practical value is the thorough treatment of syphilitic patients. Unfortunately their treatment is usually not carried out for a sufficient length of time. It would be a great help toward protecting the community from syphilis if every general hospital would make an especial effort to treat syphilitic patients and if additional opportunities were furnished toward the same end in all parts of the city. If dispensary classes for this sole purpose were arranged so that the patients would lose a minimum of time, and could call at an hour best

suited to their work, they would keep up their treatment for a longer period than at present and the spread of the disease would be greatly limited.

At the Surgical Society, October 25th, Tuffier described a posterior gastro-enterostomy performed on account of a pyloric tumor. The operation was entirely successful. Some weeks later no tumor could be felt, and one is, therefore, justified in concluding that it was of benign character. The operation showed that it is quite unnecessary to employ clamps to keep back the contents of the stomach or intestine. The tension upon these parts as they are drawn out of the wound is sufficient to prevent escape of their contents. It is a good thing to wash out the stomach after gastro-enterostomy has been performed. Annoying vomiting may be cured in this way and lavage will show the amount of hemorrhage which has taken place into the stomach, and will also remove the blood. Before making up his mind that a tumor of the stomach has disappeared the surgeon should be sure that it is not concealed beneath the ribs, as a mistake of this nature has more than once occurred.

Poirier mentioned an instance in which he had been deceived in the disappearance of a tumor of the umbilical region. Three months later he found a tumor under the ribs which was doubtless the same one, drawn up there by the contraction of the gastro-hepatic epiploon due to infiltration of the neoplasm.

Schwartz saw a gastric tumor disappear within four weeks after the performance of a gastro-enterostomy. He concluded that it was benign, and of an inflammatory nature. When he saw the patient again, less than a year later, he felt nodules, which he was sure were metastatic ones. The tumor was undoubtedly cancerous and had been drawn under the ribs by the retraction of the pylorus.

Ricard spoke of the importance of stopping all hemorrhage. He lost one patient after pylorectomy from bleeding into the stomach. It is not sufficient to rely upon the suture to control all bleeding points. The larger vessels should be separately tied.

On November 8th Routier showed a patient upon whom he had operated for extra-uterine gestation. As she had had several chills, each one of which had been followed by a rise in temperature and an increase in the size of the tumor, he was surprised to find that there was no suppuration but simply an aseptic hematocele. No cause, other than the hemorrhages, could be assigned for the rise of temperature.

Pozzi said that hemorrhage is accompanied by a fall in temperature, but that the absorption of effused blood may cause it to rise.

Tuffier treated a patient with hemothorax. A rise in temperature made him suspect suppuration and he aspirated. Aseptic blood was withdrawn. In this case the rise of temperature followed the hemorrhage by a considerable interval.

At the session of November 22d, Nelaton advocated resection of the hip-joint for coxalgia. The results obtained in adults and adolescents compare favorably with those obtained by conservative methods.

Felizet traced one hundred children who suffered from coxalgia in infancy and found that all excepting twelve of them had died of the disease or its complications. Under such circumstances a radical operation is not out of place, and he has performed it on three hundred children. The results have been generally satisfactory. The shortening is usually not more than one to two inches, but it may reach two and five-tenths to three and five-tenths inches. Even with the maximum shortening it is easy for the patient to walk if he wears a suitable apparatus.

Kirmisson took quite a different view of the subject. He advocated conservative treatment; early injections of iodoform in ether, etc., rather than operation, especially in the case of children. Many times resection is followed by a sinus because the operator is not able to remove all of the diseased tissue. He had recently examined ten patients who had undergone resection of the hip-joint for tuberculosis. Three of these patients presented fistulæ; the thigh in four was held at a vicious angle, while no one of the ten had less than two and one-half inches of shortening, and in some of them the shortening amounted to six inches. It is often no advantage to have mobility at the hip-joint, as a patient may be prevented from walking by this very mobilty. December 6th the discussion of this subject was continued. Schwartz reported a successful excision of the hip in a child aged fifteen years. Ten years later there was only one and three-quarter inches of shortening, and the patient walked and rode a bicycle with ease. By operation upon patients in whom the disease is more extensive, such a good result cannot always be obtained. He had recently operated upon such a one a second time without getting beyond the disease.

Consolidation in ununited fractures brought about by the administration of the thyroid gland was the subject of some remarks by Potherat, who reported that two patients had been thus treated with success. The treatment lasted from ten day to two weeks. One patient developed symptoms of cerebral hemorrhage on the eleventh day. Other observers have reported similar successes with thyroid medication, which cannot, however, be unreservedly advocated on account of the alarming symptoms which follow excessive doses.

At the Medical Society of the Hospitals, November 10th, Joffroy described some of his successes in curing patients of the morphin habit. He laid down two all-important principles: (1) Never attempt to demorphinize a cachectic patient. First improve his nutrition and build up his strength; (2) keep the patient in ignorance of the precise day in which the reduction of the

drug begins, and continue this plan until the poison has been completely suppressed. The fear of suppression of the drug greatly aggravates the symptoms caused by its withdrawal.

On November 17th Gaucher gave the history of a patient whose death had been caused by the subcutaneous injection of calomel to the amount of two grains. Four months elapsed between the injection of the mercury and the death of the patient, but owing to the insoluble character of the mercury its absorption would necessarily be slow.

At the session of November 24th, Widal spoke of Kernig's sign, produced by meningeal hemorrhage. The subject was a man aged thirty-eight years, who suffered an apoplectic stroke while apparently in full health. He regained consciousness in some hours. He presented neither fever, paralysis nor muscular contraction, but complained of an intense headache and lumbar pain. The pupils were slightly dilated. Kernig's sign (ability to hold the leg extended on the thigh, while lying down, but inability to do so while sitting in a chair) was present and the question of meningeal hemorrhage was at once raised and settled affirmatively. Nine days later the patient died. Much fluid blood and a large clot were found in the subarachnoid space and the spinal column was full of blood. Neither the convolutions at the base of the skull nor upon its convexity had been pressed upon by the blood. This case showed that Kernig's sign may exist without inflammation.

At the Biological Society, October 28th, Oninus stated that he had long believed that the value of ipecac in the control of pulmonary hemorrhage is due to the nausea which it produces. He has employed it with complete success in metrorrhagia. His practise is to give every two hours a capsule containing 1.6 grains of Dover's powder and one-sixth grain of powdered ipecac. The administration of such capsules until nausea develops will check the abnormal flow of blood and menstruation will cease naturally. During the menstrual intervals the patient should take one powder at bed-time.

At the session of November 11th, Tuffier mentioned the success he had in producing anesthesia by the injection of cocain into the lumbar vertebral canal. By this means he was able to remove an enormous recurrent sarcoma of the hip absolutely without pain. In six minutes from the time the injection was made all sensation below the umbilicus had been lost. Sensation for pain did not return for an hour. This new method of producing anesthesia below the umbilicus merits further trial in suitable cases. The anesthesia produced is perfect, but the amount of cocain employed (2 centigrams in 1 or 2 c. c. of water) is not without danger, as shown by the vomiting and headache produced in certain cases in which it was employed. Instances of vertigo and collapse were not uncommon in the earlier use of cocaine hypodermatically for simple operations.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held November 17, 1899.

A. B. Judson, M.D., Chairman.

Deformity of Pott's Disease.—Dr. W. R. Townsend presented a boy, fifteen years of age, who developed Pott's disease in the lower dorsal and upper lumbar region six years ago. Two years ago, having recovered with considerable posterior curvature, after treatment by the plaster-of-Paris jacket, he fell from an ice-wagon, striking on his head. Plaster of Paris was reapplied. He presented a projection on each side at about the level of the twelfth dorsal vertebra. The spinous processes could be felt between the elevations, which were very marked and might have been supposed to be calluses following fracture of the ribs near the vertebral column.

Dr. R. H. Sayre said that in addition to the anteroposterior curve there was lateral displacement, which might well have been the result of vertebral fracture.

Dr. S. Ketch said that the bony projections were secondary formations, the result of traumatism and were distinct from the spinal disease.

Rickets in a Dwarf.—Dr. Townsend presented a girl, six years of age, 35 inches in height, the average height at that age being between 40 inches and 42 inches. There was enlargement of the epiphyses of the long bones, with an enlarged head, prominent chest and protruding abdomen. She was a mouth-breather, and failure to grow normally might have been due partly to adenoids and insufficient oxygenation. There might have been obstruction in the posterior part of the nose, although the result of inspection anteriorly had been negative. The characteristic appearance of the skin and facial expression of cretinism were absent.

Dr. Sayre suggested enlargement of the air-passage by treating the tonsils and adenoids.

Dr. Ketch said it would be of interest to know whether this relief would promote normal growth.

Dr. H. S. Stokes said that the patient was probably a constitutionally lymphatic child, one of a class of patients in whom the administration of anesthetics is attended with danger. Without hastily making a positive diagnosis of this condition, he suggested that the use of anesthetics be preceded by a thorough physical examination.

Pott's Disease or Fracture.—Dr. Townsend presented a girl, six years of age, with a very obscure history. Two years ago, when living with her grandmother, after an accident in which she fell down a flight of stairs, striking the back of her neck, a bony prominence had been noticed, with difficult respiration and a habit of support-

ing her head with the hand placed under the chin. Kyphosis was marked, as shown by the accompanying cut, involving the sixth and seventh cervical and the first and second dorsal, with a depression of the upper cervical vertebra.

Dr. A. B. Judson thought that the number of the involved vertebrae pointed away from fracture, and towards Pott's disease. The elements of diagnosis in orthopedic cases might be arranged in the following order of relative importance: (1) Signs (objective); (2) symptoms (subjective); (3) history as given by the mother, and (4) history as given by the grandmother.

Dr. Sayre said that a forward position of the head in cervical Pott's disease is frequently attended by difficult breathing. He thought, however, that the child had suffered a fracture and recalled the case of a man who had fallen down stairs, striking the back of his head. Partial paralysis of the arms developed from pressure. A

Pott's Disease or Vertebral Fracture.

diagnosis of Pott's disease had been made, but the signs and history indicated a fracture.

Dr. Townsend said that the treatment, at least, is not in doubt. The affected vertebra should have complete rest, either by a plaster jacket and head-spring, or by a posterior spinal support and chin-piece. The latter would be less conspicuous and give better support, with or without the addition of supports going up the back of the head, as might be determined by the progress of treatment, which should be prolonged until the disappearance of all signs of an acute condition. Ultimately the patient would carry the head erect without much deformity, as is the rule in cervical disease thus treated.

Durability of Plaster Jacket.—Dr. Stokes related the history of a case of Pott's disease in a girl who was four years of age when first seen in September, 1894. The duration of the disease was two months. The tenth dorsal vertebra was affected. The plaster-of-Paris jacket had been applied anew seven times at intervals of from eight to fifteen months, the average being eleven months. No pain or discomfort had been traced to the apparatus. At the last application, on October 13, 1899, it was found that a small stone had slipped into the jacket and caused an erosion which had healed in a few days.

Dr. Townsend had seen plaster jackets that had been worn two years.

Dr. L. W. Ely cited a case in which the jacket had been reapplied at intervals of thirteen and eight months without excoriation.

Dr. Sayre referred to the case of a child who had worn a solid jacket for two years.

Dr. H. Gibney cited three cases: (1) A boy seen in 1891; aged four years; location, middle and lower dorsal region; emaciation, and a large psoas abscess. The first jacket was worn two months, the second one year, and the third had been applied two months ago. There had been no increase of deformity, the abscess had been to a large extent resolved and the general health had improved. (2) A boy, aged six years; tenth dorsal; first jacket worn three months; the second, eleven months, and the third was applied three months ago. The local condition was favorable, and the health had improved. In the third case, that of a woman of twenty-seven years, a firmly-fitting jacket had been worn for a year without inspection, with freedom from pain and discomfort, and with good effect.

Dr. Sayre cited two cases in which patients had not done well with jackets that were removable, but which progressed favorably towards recovery when the immovable dressing had been applied. In both cases the treatment had been modified in its early stages by the overweening kindness of the grandmothers of the children. He had seen cases in which efforts to replace comfortable jackets by new ones had not been brilliantly successful, it having been a long time before the patient was again made comfortable. For obvious reasons a jacket should not remain in place too long on a child who is growing fast.

Dr. V. P. Gibney said that more important than the question of time is that of applying the jacket so as to give good support and avoid excoriations. A jacket well applied would not disturb the skin and should be durable. In the case reported by Dr. Stokes the trifling excoriation had soon healed and a cure had been effected by the prolonged splinting of the back.

Dr. Sayre said that excoriations can generally be avoided by a careful application of the jacket.

Dr. Stokes said that the percentage of excoriations is small, and in ten cases the trouble had been due to the jacket in four cases and to foreign bodies, little things such as pennies and buttonhooks, in six cases. Excoriations caused by a jacket are evidences of a want of skill and experience on the part of the surgeon.

Dr. Sayre said that the skin could be kept clean and healthy by passing a whalebone inside of the jacket and so pulling up and down a fine handkerchief dampened with alcohol.

Dr. H. Gibney said that a solid jacket should be

applied over a long strip of linen or gauze six inches wide, which could be daily wet with alcohol and drawn back and forth.

Plaster and Steel.—Dr. Ketch said that the condition of the skin should be made the subject of stated investigation, not to prevent excoriations, but to ascertain whether the diseased vertebral column is being given all the mechanical support which the toleration of the skin warrants. The use of a steel apparatus facilitates an occasional and desirable estimate of possible decrease or increase of deformity, which is impossible with the immovable dressing. Changes in the shape of the patient, from growth or otherwise, should meet with corresponding changes in the pressure made by the apparatus.

Dr. Townsend said that the frequent removal of the jacket or brace is one of the worst things that can be done. It is not practised in the treatment of fractures. In Pott's disease we seek proper anchylosis at the seat of the disease. We therefore immobilize the vertebral column. So long as the jacket is clean and the skin healthy we can forego the doubtful advantage to be gained by frequent inspection and rely on the effectiveness of the apparatus.

Dr. Ketch said that the removal of the brace for alterations, when done with ordinary care, cannot delay or interfere with consolidation. The more scientific procedure is to use an apparatus which is under intelligent surgical control.

Dr. V. P. Gibney had failed to see that important benefits can be gained by taking off the apparatus from time to time. If sure of the diagnosis and of a well-fitting plaster jacket, he is confident of a good result.

Dr. Sayre said that in the cervical region, and anywhere above the tenth dorsal, a jacket should be supplemented by the jury-mast and by a brace to control the shoulders. Traction and control of the movements of the head are very important. He often makes use of a metal and leather support to make a base for the jury-mast.

Dr. H. Gibney commended the method of application in which the patient rests on two untempered steel rods bent to fit the shape and elevated from the table, partly held up by two assistants, who make gentle traction, the rods being drawn out while the plaster is setting.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held December 5, 1899.

Frederick Peterson, M.D., President, in the Chair.

Multiple Sclerosis and Muscular Atrophy.—Dr. Graeme M. Hammond presented a case of multiple sclerosis occurring in the person of a man, thirty-eight years of age, exhibiting symptoms resembling those of progressive muscular atrophy. This combination is quite rare. The patient is a locomotive fireman by occupation and has a good personal and family history. About one month after an attack of the grip, ten years ago, his present trouble began. The first symptom was a paralysis of the internal rectus of the left eye, and this was followed by weakness of the left superior and the right internal rectus. At the present time, in addition to these symptoms, there is left hemianopsia. About one year ago there occurred a sudden loss of smell on both sides. About six years ago he begun to show symptoms of locomotor ataxia. The knee-jerks were absent. Last January he noticed weakness in the little and right fingers of the right hand. This weakness extended to the other fingers and was accompanied by atrophy. The atrophy is now well marked in both upper extremities, and fibrillar twitchings may be noticed in the affected muscles. These muscles respond slightly to the galvanic current but not at all to the faradic. This history is very characteristic of multiple sclerosis. In 1897 a similar case was reported in one of the German journals. In the case presented, true intention tremor and scanning speech are not present. The patient may be suffering from a progressive muscular atrophy engrafted upon a multiple sclerosis, but it is also possible that the sclerotic changes have taken place in an unusual position in the anterior horns. The optic nerves have remained normal.

Dr. B. Sachs said that it is his impression that the case may be almost anything else than multiple sclerosis. This diagnosis does not seem justified in the absence of nearly all of the cardinal symptoms. The case is certainly puzzling, but reminded one of a case of tabes with progressive muscular atrophy, and the President of this Society reported such a case some time ago.

Dr. Joseph Collins said that he hesitates to make this diagnosis after a hasty and superficial examination, nevertheless he cannot but feel that this is a case of locomotor ataxia plus progressive muscular atrophy. It is possible that it is an example of syringomyelia and tabes, for he has had such a case under observation for a long time.

Dr. George W. Jacoby agreed with the last two speakers. Certainly the symptoms in the upper extremities and the optical symptoms resemble those of a nuclear affection, while the symptoms presented by the lower extremities are like those of tabes. It is rather presumptive to make a diagnosis after Dr. Hammond has studied the case so carefully.

Dr. Frederick Peterson thought this patient presented all the symptoms of locomotor ataxia. Atrophies of this kind are not very uncommon in locomotor ataxia. Several years ago he had exhibited to this society a case of typical locomotor ataxia with three symmetrical quadrants of vision lost, so that the person saw out of only one-quarter of each eye. He therefore looks upon the case as a locomotor ataxia presenting the unusual symptoms already cited.

Dr. Hammond replied that at first he had also looked upon his case as one of locomotor ataxia with ocular symptoms, but, on studying it more

carefully, he could not find the slightest indication of syphilitic infection, the man having indeed been singularly free from previous illnesses of any kind. He was temperate in his habits, was not neurotic, and presented an unusually good personal history. Again, his tabetic symptoms have not been at all prominent; the Romberg symptom has been hardly noticeable, and there have been none of the bladder or sexual symptoms of tabes. The fact that there have been lesions of the optic, the third, and the olfactory nerve, coming on respectively at intervals of several years, he looks upon as proof that this is a sclerosis affecting these different nerves. An affection of the posterior columns in disseminated sclerosis is not at all unique. The atrophy in the hands, is, however, decidedly unique.

Intracranial Growth.—Dr Phillip Meirowitz presented a man, thirty-eight years of age, who had come to him on December 1, 1899, complaining of amblyopia of the left eye. He is entirely blind in the right eye from an injury inflicted with a piece of steel. The disturbance of vision first appeared in the summer of 1898 and reappeared four months ago. These "blind spells" come on several times a day and last about eight minutes each time. They have continued altogether for about six weeks and have been unaccompanied by pains. A tremor in the right upper extremity also developed about the same time as the trouble with the eyes. Jerking of the right arm has been quite marked at night. Vertical headache has been present and quite troublesome some months ago but is no longer present. About the middle of last July he was seized with attacks of vomiting after taking food, but improved under milk diet and the administration of iodid of potassium. About this time he had a sudden loss of consciousness and again two or three months ago. There is no distinct history of syphilis. Examination shows dilatation of the left pupil and good reaction to light with absence of nystagmus. Tremor of the right arm is quite marked and is aggravated by movement. His gait is good; the knee-jerks exaggerated; there is no ankle-clonus. There are no sensory disturbances. Dr. Valk has examined the eyes with the ophthalmoscope and found a papillitis. There is no mental dulness and no impairment of the memory. The speaker is of the opinion that there is an intracranial growth and believes that its location in the cerebellum accounts for most of the symptoms. He is inclined to believe that it is a syphiloma because of the effect of treatment with the iodid and the lack of definiteness regarding a possible syphilitic infection.

Dr. S. B. Onuf said the patient was under his care at the time that he received the iodid. There was then a staggering gait, a marked intentional tremor, increased knee-jerks and ankle-clonus on the right side. His eye showed marked choked disk and a number of retinal hemorrhages. He at first hesitated between a diagnosis of tumor and multiple sclerosis. Dr. Coffin had expressed the opinion that the shape of the hemorrhages—small and wedge-shaped—pointed rather toward syphilis. The man was then put upon rapidly increasing doses of the iodid and improved promptly. The dilatation of the pupil and the intentional tremor were noticeably controlled by this treatment. He did not doubt that the trouble was syphilitic, but could not accept the theory that all of the symptoms could be explained by one syphiloma.

Dr. Meyrowitz replied that Dr. Francis Valk, in his recent ophthalmoscopic examination, found the retina entirely normal. The absence of disturbance of speech and of nystagmus and the presence of papillitis seem to him sufficient to exclude multiple sclerosis. It is, of course, quite possible that there are a number of lesions, but in cases in which the symptoms can be explained by one lesion this, of course, seems the more rational.

Tumor Compressing Cauda Equina.—Dr. B. Sachs reported two cases of compression of the cauda by tumor, in both of which the symptoms had been relieved by operation. The first patient was seen on September 3, 1897, in consultation with Dr. Wyeth. The second patient presented himself at the Mount Sinai Hospital in the service of Dr. Meyer. The first patient, fifty-six years of age, has been suffering for eighteen months with severe pains in the lower extremity and, more recently, with spasm of the muscles. He was shot in the leg during the Civil War. When seen by the speaker he presented marked cachexia, severe pain and violent spasm. The pain was neuralgic in character and radiated from the lumbar region of the spine down the posterior aspect of the thigh to the foot. The spinal column was not specially sensitive except over the second lumbar vertebra, at which point pressure elicited pains like those complained of ordinarily. There was a distinct diminution of tactile pain and temperature sense at the upper and inner portion of the right thigh. The right knee-jerk was absent. The vesical and rectal reflexes were not impaired. That the neoplasm was extradural was probable because, if intradural, the symptoms would have been more symmetrical. He had urged Dr. Wyeth to operate for the removal of the growth and the operation had been done at once. Upon exposure of the spinal canal a tumor the size of a small cherry was revealed, adherent to the dura and bone. Microscopical examination of this mass showed it to be an alveolar sarcoma. As much as possible of the diseased tissue was removed. Five days after operation the patient was able to be up and around, and had been remarkably comfortable. The spasms had ceased. One month after operation the patient returned to his home in the South.

The second patient, thirty-nine years of age, was admitted to the Mount Sinai Hospital on October 9, 1899. Some years ago he was told he had pulmonary tuberculosis and had lived in California until apparently cured. He was of

emotional temperament, and had come to the hospital with a diagnosis of locomotor ataxia. About one year ago his first symptoms appeared. Examination showed normal reaction of the pupils; no tremor of the tongue or face. There was a distinct kyphos involving the twelfth dorsal and three upper lumbar vertebræ, but there were no tender points except between the third and fourth lumbar vertebræ. There was no marked interference with the vesical and rectal reflexes. The physical signs in the lungs were suggestive of tuberculosis. There were no strictly ataxic symptoms, but there was distinct paresis of the lower extremities. The strictly unilateral character of the sensory changes pointed to a probable growth in the lower portion of the spinal column, but, in deference to those who thought it possible that there was a tuberculosis of the spine, suspension and fixation of the spine had been attempted. This has not yielded any results. The disease is evidently progressive and mercurial and iodid treatment has proved negative. On November 10th, at his suggestion, Dr. Gerster attempted laminectomy on the second and third lumbar vertebræ. At this operation a gelatinous mass was exposed and it was found that the body of the third lumbar vertebra had been invaded by the disease. The tumor extended only to the lower margin of the second vertebra. The tumor was removed. It had evidently compressed the cauda equina. Sections of the tumor showed it to be a small-cell sarcoma Three days after operation sensation in the leg seemed to be improved. Improvement had been steady, but the patient has been compelled to remain in bed. There is reason to hope for at least a temporary recovery—certainly life has been prolonged by the operation.

Commenting upon these cases, the speaker said the first case had been diagnosticated as a chronic neuralgia previous to coming under his observation. The bilateral distribution of the pain, the absence of marked vesical and rectal symptoms seemed to point to the cauda equina and not to the lumbar enlargement, and the tender spot had served as a valuable guide in both cases. There are few chronic spinal processes that follow the slow course of such spinal tumors. An exploratory laminectomy, if properly done, is practically harmless, particularly if done in the lumbar or dorsal regions.

Dr. Joseph Collins said the cases presented should be a cause for much congratulation on the part of the reader of the paper, as well as of the surgeon who operated. The history of the first case pointed unequivocally to the presence and location of an intraspinal tumor, and he was glad that Dr. Sachs had had the courage to urge operation. He was reminded of a case seen by him in which he had endeavored to have a glioma operated upon, but the surgeons had arrived too late to be of assistance. He felt sure that the mortality in these cases was not so great that neurologists should not be on the alert to diagnose them and urge operative intervention.

Dr. Peterson added his congratulations to those of the last speaker. Tumors in this particular locality were more difficult of diagnosis than in other portions of the cord. One important feature of the paper is the aid that the sensitive area or the deformity afforded in establishing the diagnosis.

Dr. Sachs, in closing, emphasized the point that even if the sensory changes were very slight they should be reckoned with in making the diagnosis. This was well exemplified in the first case. Another point insisted upon was that he had managed by pressure upon a definite point to elicit the same pain as that of which the patient had complained. This had been extremely well marked in the first case.

Dysphrenia.—Dr. William Hirsch read a paper with this title. The term "dysphrenia" has been applied to the secondary or sympathetic psychoses in contradistinction to the idiopathic or mental diseases, such as mania and melancholia. The secondary psychoses, which are produced by bodily diseases, are not characterized by the same uniformity of symptoms that mark the idiopathic variety. In the secondary psychoses there are frequent remissions with perfect lucidity during the course of the disease. Outbreaks of violence may be quickly followed by stupor. A further characteristic is the occurrence of somatic symptoms as loss of pupillary or patellar reflexes, rise of temperature, irregularity of the heart action and certain vasomotor phenomena, such as edema. In the secondary psychoses, the interstitial tissues and particularly the blood-vessels are the ones at first and mainly affected. This is in accordance with the accepted pathology of the systematic spinal diseases. The changes in the interstitial tissues are produced by the diseases starting outside of the brain, such as the acute febrile diseases. There are a few cases in which, purely from the mental symptoms, one is justified in making a diagnosis of dysphrenia, even though ignorant of the exact nature of the underlying bodily disease. A case of this kind was then reported by Dr. Hirsch. The patient was a young, neurotic girl, seen by him first on September 5, 1896. She then presented the condition of hallucinatory confusion. After an interval of quiet, on February 17, 1897, she became violent, and developed hallucinations of hearing and sight. At this time the temperature was normal. After about ten days she became stupid, her pupils were contracted, and the pulse was sixty. After about one week, automatic movements of the hands and head appeared. On March 14th menstruation came on and she quickly became normal and remained well for ten days. In April, 1897, she was given thyroid extract and quickly recovered. She remained well for nearly two years. On February 2, 1899, she unexpectedly developed the same violent symptoms as before. She showed some transitory improvement again under the administration of thyriod extract, but soon passed into a condition of dementia. After about three months she be-

came quieter; the pupils and patellar reflexes returned; the temperature became normal and her breasts, which had been much enlarged, returned to their natural size. Since that time her mental state has been good. The clinical features of this case evidently do not correspond to any primary psychoses. A loss of reflexes is generally considered as indicative of permanent change, but it is not impossible that this symptom may exist in functional disturbance. In the case just reported the menstrual disturbances are not the cause but a symptom of the disease, as in the fourth or worse attack menstruation had little or no effect on the mental state. The speaker suggested that the term "originary (or idiopathic) dysphrenia" should be applied to those cases, which, in their clinical aspects, resembled those known to be produced by toxic or infectious agents, but in which no cause for such infection could be found.

Dr. Brown said that he had been deeply interested in the paper and had seen a number of somewhat similar cases presenting a physical basis for the mental disorder. In some cases of even very severe mental disease the mental symptoms clear up during the later stages, for example, of tuberculosis.

Dr. Mary Putnam-Jacobi asked Dr. Hirsch if he looked upon general paresis as a secondary psychoses, and also in what way the case of dysphrenia reported by him differed from recurrent attacks of hysterical insanity; also how far the failure to distinguish personality was really a mental symptom and how much the result of personal caprice.

Dr. B. Sachs said that probably all present had seen cases similar to the one described. He has had under observation a number of women between the ages of fifteen and twenty who have passed through very remarkable periodical mental changes. He was much impressed with the suddenness with which these changes had occurred. All of these patients were members of strongly neuropathic families. They passed quickly from a condition of mania to one of depression. A patient now under his care has regularly had periods of six months or more in which she has been in a condition of maniacal excitement, and has then very suddenly passed into a condition apparently normal, but really only a stepping-stone period of excitement. It was questionable, in his mind, whether the class of cases spoken of in the paper represented a distinct entity in mental diseases. Such marked physical changes as described in the paper have not come under his observation.

Dr. Peterson expressed his belief that dysphrenia would be a convenient term for those cases that would be difficult to describe under other names. The trouble is that these terms in psychopathy are usually founded upon clinical symptoms, with but little reference to the pathology, so that after a time the word comes almost to include all insanity. Last summer, at Heidelberg, he found about four varieties of insanity recognized, *viz.*: paresis, senile dementia, catatonia, and dementia precox. About fifty per cent. of the cases in Germany at the present time are called catatonia, and the balance are included under the term dementia precox.

Dr. Hirsch said it was certainly remarkable how many insane patients pass through a disease like typhoid fever without developing any mental symptoms—indeed, the patient whose history has been given has just passed through a typhoid fever in this way. He, too, recognizes the great evil that results from introducing names into psychiatry, but dysphrenia is not a new name, and certainly is useful in connection with a case like the one reported, which could not be well placed in any other classification. Dr. Sachs has referred particularly to circular insanity—to cases essentially chronic in their nature—but he had been discussing cases that were really acute. The mental disease consists of a series of psychopathic conditions. The diagnosis of dysphrenia can only be made from a detailed history and long study. By a primary psychosis he means a mental disease originating in the parenchyma of the organ; by a secondary psychosis, one originating in the interstitial tissue; hence general paresis is a secondary psychosis.

SELECTION.

A SURGICAL EPISODE OF THE PENINSULAR WAR.[1]

To understand something of the grim realities of war we must place it, as it were, under the microscope by studying records of individual cases. Such a case may be found in the memoirs of Captain Boothby,[2] who was wounded in the Peninsular War, and left in the hands of the enemy. The story of his sufferings will further serve to give an idea of military surgery in the early days of the present century.

Captain Charles Boothby was an officer of the Royal Engineers, who was present at the battle of Corunna, and in July, 1809, was wounded at Talavera, his leg being shattered by a musket ball. After the battle he was carried by four men on a bier to the town of Talavera.

The men were hampered by their arms and accoutrements, and the irregular motion caused the wounded man excruciating agony. The road lay through a thick wood; alarms of ambuscades were frequent, and the bearers often laid their burden on the ground while they reconnoitred. It was three hours after the receipt of the wound that the hospital was reached. From the hospital he was carried to a lodging in the town. There a surgeon (Mr. Bell) cut off his boot, and, having examined the wound, said there was no chance of saving the leg, and the amputation must be above the knee. He passed a night of agony, and at dawn Mr. Bell went to the hospital to seek an-

[1] From the British Medical Journal, December 23, 1899.

[2] A Prisoner of France. The Memoirs, Diary, and Correspondence of Charles Boothby, Captain Royal Engineers, during his last campaign. London: Adam and Charles Black. 1898.

other surgeon, Mr. Higgins. It was several hours before the latter came, and when he at last made his appearance it was only to tell Boothby that there was but one case of instruments, which it was impossible for him to bring from the hospital, while crowds of wounded, both officers and men, were begging for assistance.

Higgins came again in the afternoon, bringing with him Bell and another surgeon named Gunning with instruments. Boothby resigned himself into their hands. The surgeons, having examined the wound, went to another part of the room to consult, after which they withdrew "to bring the apparatus," as Boothby thought. Hours, however, passed without their return, and Gunning, having at last been found, said he was too much occupied. Boothby then said to his servant to go again into the street, and bring the first medical officer he happened to fall in with. He soon returned, bringing with him Mr. Grasset, of the 48th Regiment. He on examining the wound declared that he was by no means convinced of the necessity of the amputation, and would on no account undertake the responsibility of so serious a measure without consultation.

The conversation that followed gives such a picture of the surgery of that day that it may be quoted:

"But," said I, "I suppose an attempt to save the leg will be attended with great danger?"

"So will the amputation," answered Mr. Grasset; "but we must hope for the best, and I see nothing to make your cure impossible. The bones, to be sure, are much shattered, and the leg is much mangled and swollen; but that may all suppurate and come right, so that I cannot think of amputating without more advice. But have you been bled, sir?" he asked.

"No," said I.

Mr. Grasset thought bleeding absolutely necessary, and at Boothby's request he bled him in the arm.

It appeared afterwards that Gunning's departure was due to his conviction that gangrene had already set in, and that it would be cruel to disturb Boothby's dying moments by a useless operation. As the wounded man had taken nothing but vinegar and water since his misfortune, the bleeding was succeeded by an interval of "painful unconsciousness."

In the evening another surgeon, named Fitzpatrick, came at his request to see him. The surgeon said, as soon as he looked at the wounded limb, that if he had him in London he might attempt to save it, but in the circumstances it would be hopeless. Asked if he had come too late, the surgeon said "No." But in this, according to Boothby, he dissembled, as there were already strong symptoms of lockjaw, which did not disappear till many hours after amputation.

It was arranged that the operation should take place in the morning, and on Boothby asking if something could not be given him to ease his sufferings, which were scarcely endurable, the surgeon took a towel, and, soaking it in vinegar and water, laid it on the wound, which gave considerable relief.

Fitzpatrick stayed with him till morning, changing the lotion at intervals. The account of the operation may be given in the patient's own words:

"Fitzpatrick and Miller of the Artillery, Higgins and Bell, staff surgeons, were the gentlemen who at 9 o'clock prepared to perform this serious operation upon me. Having laid out the necessary instruments they put a table in the middle of the room and placed on it a mattress. Then one of the surgeons came to me and exhorted me to summon my fortitude. I told him that he need not be afraid, and Fitzpatrick stopped him, saying he could answer for me. They then took me to the table and laid me on the mattress. Mr. Miller wished to place a handkerchief over my eyes, but I assured him that it was unnecessary—I would look another way. The tourniquet being adjusted, I saw that the knife was in Fitzpatrick's hand, which, being as I wished, I averted my head.

"As I do not choose to gratify the curious (at the expense of the feeling) reader, I shall not describe an operation the details of which are perhaps more shocking to reflect upon than to experience. But, as it is a common idea that the most painful part of an amputation lies in sundering the bone, I may rectify an error by declaring that the only part of the process in which the pain comes up to the natural anticipation is the first incision round the limb by which the skin is divided—the sensation of which is as if a prodigious weight were impelling the severing edge. The sawing of the bone gives no uneasy sensations, or if any, it is overpowered by others more violent."

"Is it off?" said I, as I felt it separate.

"Yes," said Fitzpatrick; "your sufferings are over."

"Ah, no; you have yet to take up the arteries."

"It will give you no pain," he said, kindly; and that was true—at least, after what I had undergone the pain seemed nothing.

"I was carried back to my bed free from pain, but much exhausted. The surgeons complimented me upon my firmness, and I felt gratified that I had gone through what lay before me without flinching or admitting a thought of cowardly despair. I desired that the amputated limb might be brought to me that I might examine the wound. The request was opposed with some force by the surgeons; but I persisted, and found a certain satisfaction in observing that the limb wore an appearance to the last degree mangled and hopeless. This moderated my tender sorrow at beholding for the last time that active and invaluable servant."

For some time after the operation the dangerous symptoms increased, his stomach refused sustenance, and a constant hiccough was recognized by the surgeons as a fatal prognostic.

In the night of the 30th he managed to retain some mulled wine strongly spiced, and in the morning he took two eggs. This was the turn;

his unfavorable symptoms subsided, "and the flowing stream of life began to replenish by degrees its almost deserted channels." So he continued to improve until August 3rd, when in the movement of the troops his friends had to leave him. Fitzpatrick stayed till the 4th. In the morning he promised to engage for Boothby the attendance of Higgins, who was left senior surgeon, but a rumor that the French were approaching spread a panic through the town, and Fitzpatrick appears to have left in a hurry.

The battle of Talavera resembled that of Glencoe, as the victors were afterwards obliged to retire and leave their wounded to a vanquished enemy. An order was given that the wounded in the hospitals who were able to move should set off instantly for Oropesa, as the French were at hand.

"The sensation this notice produced is beyond all description. I lay perfectly still. I had made up my mind that it would be better to fall into the enemy's hands than to attempt to go away. Other men in situations like my own had placed themselves across horses and mules, and fruitlessly attempted to escape. The road to Oropesa was covered with our poor, wounded, limping, bloodless soldiers. On crutches or sticks, with blankets thrown over them, they hobbled woefully along. For the moment panic terror lent them a force inconsistent with their debility, their fresh wounds, and their recent amputations. Some lay down on the road to take their last sleep. The rest, unable to get further than Oropesa, fell afterwards into the hands of the French when their troops entered that town."

Boothby admits that he was ill at ease, especially from the fear that the panic terror that had been communicated to the hospitals might extend to the surgeons, whose assistance, he says, was of more to him than any other consideration. The evening of the 4th, however, closed in quietness uninterrupted by the French, and Boothby had a visit from the senior medical officer, Mr. Higgins, which gave him great comfort, as the conversation of the surgeon taught him "to confide in his conduct."

Like a prudent man Boothby employed the interval of tranquility, short as it was, in laying in a stock of provisions. Mr. Stanniland, assistant surgeon of the artillery, said the French were coming, and Mr. Higgins had gone out to meet them. In about an hour Mr. Higgins came in and made the following announcement:

"I have been out of town above two leagues, and can see nothing of them. If, however, they do come, they will have every reason to treat us with attention; for they will find their own wounded lying amongst ours, provided with the same comforts, treated with the same care. I have been completely round myself to see that the treatment of their officers and men was in every respect upon the same footing as our own, so that they will have no possible pretext for complaint; and I can boldly claim their protection and respect. Whenever they come, I shall meet them and solicit the General to visit the hospital with me."

When the French did come, on August 6th, Higgins rode out to the General who commanded the cavalry, and on making the representation he had preconcerted, found the General full of the most noble sentiments. He said the fortune of war had thrown some Englishmen into the power of the French, who would be incapable of abusing it. He added:

"And as for you medical gentlemen who have been humane and manly enough not to desert your duty to your patients (many of whom are Frenchmen) in the hour of difficulty and distress, and have done us the honor to trust yourselves in our hands, not the smallest constraint will be put upon your motions. Stay amongst us as long as you please; go when you will. You are as free as the air you breathe. And whenever you think proper, our safe conduct and unfeigned thanks shall attend you to your countrymen."

Boothby adds the following glowing eulogium of the conduct of the devoted medical officer:

"We had afterwards reason to know how much we were indebted to this good beginning arranged by Mr. Higgins. Only their wish to support some appearance of consistency checked their natural disposition to ill-treat us. Throughout Mr. Higgins displayed the character of no common man. To be loaded with the charge of such groaning multitudes—almost wholly unprovided with medicines, medical stores, or provisions—would have been regarded by most medical men as a task of no common arduousness; and to perform it at the expense of personal liberty and all prospects of advancement was a case of peculiar hardship. But to prepare for the approaching crisis—determined to ride forth and parley with the enemy, and persuade him that he owes you respect, gratitude—this is the province of an officer of the first class; and Mr. Higgins in so acting—in adopting the duties of every station that happened to be vacant, in letting no office stop for want of an officer, but supplying the place of the absent and encouraging the present—discovered a manly superiority, a dauntless indifference to events that communicated confidence through every inferior branch, and secured to his suffering countrymen the blessings of a perfect medical attendance, and the protection and respect of their enemies."

"The artillery surgeon was unremitting in his attendance, meeting Mr. Higgins at my quarters invariably at 10 o'clock every morning, and their visit was usually repeated in the course of the day. As Mr. Higgins had of necessity intercourse with the French commanders, from him I heard all the news. His mind was of such a cheerful cast that it kept its tone amid all the difficulties and all extremities. Never did I receive from his presence other than consolation. Since the battle he had never taken off his clothes—seldom, indeed, had rested; was ever in want of what could never be procured; and yet no whining—no complaining—no giving up!"

On August 14th Boothby is able to announce that his stump is going on very well, and he hopes to be in Madrid in the course of two or three weeks. On August 25th he writes that his limb, after a good deal of struggling owing to a propensity in the muscles to retract, is now almost healed. The propensity here referred to required a tightness of bandage which made him suffer extremely, and broke his rest till he became accustomed to it. On October 1st he went out on crutches, attracting the notice of the French soldiers and of the Spaniards. The former invariably expressed surprise at seeing the success of an amputation which, in the hands of their field surgeons, they knew to be almost always fatal.

REVIEWS.

Progressive Medicine. A Quarterly of Advances in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D. Volume IV., December. Philadelphia and New York: Lea Bros. & Co., 1899.

The present volume of "Progressive Medicine" is, if possible, of even more general interest than the preceding numbers.

In the chapter on diseases of the stomach the review of the recent literature of gastroptosis and of dilatation of the stomach, subjects which are every day becoming of more and more interest, is very fully discussed. Stren's method of recognizing the position of the stomach by means of the slight shadow seen upon the abdominal wall during the respiratory movement, when the stomach is somewhat distended, is the latest interesting development in this subject. The patient should be placed in about the same position with reference to the light as is necessary in observing the shadow cast by the diaphragm on the thoracic wall during respiration, the so-called Litten's phenomenon.

With regard to the treatment of gonorrhea, Dr. Belfield is of the opinion that it is more the method of irrigation than the use of permanganate which gives such good results in the Janet treatment. His experience with permanganate has been unsatisfactory. He has found, however, protargol, the substance introduced some two years ago by Neisser of Breslau, to be very useful.

In the chapter on orthopedics the review of the subject coxa vera, curvature of the neck of the femur, is especially complete and up to date. This disease has been, and is yet, the cause of a good many errors in the diagnosis of pathologic conditions about the hip-joint. Although the subject is considerably less than ten years old, its literature is very extensive. The practical points necessary for the recognition of the disease and the methods of treatment suitable for various types of cases are here discussed in a manner that cannot fail to be of great service to the busy practitioner.

The discussion under diseases of the kidneys of the etiology of uremia is an extremely interesting review of recent thought and experimental work upon this subject. The principal fact brought out is that the blood-vessels in the brain, owing to the circumstance that they are not supported by firm surrounding tissues, are not so much under the influence of vasoconstrictor nerves as are the other peripheral vessels in the body. It is probable, therefore, that when all the other minute vessels are narrowed those of the brain, on the contrary, are dilated. This deprives of all value many of the present theories of the cause of uremia.

Under physiology an interesting observation is quoted from Jacques Loeb, who has proven by experiments that alkalis decidedly hasten the process of oxidation in animal tissues, and thus act as stimulants to their activity, while diluted acids have the opposite effect. He thinks the addition of small quantities of alkali would increase the beneficial effect of saline transfusion, and asks whether it would not be advisable to give alkalis in fevers to counteract the decrease in alkalinity of the blood.

In the chapter on hygiene some interesting statistics with regard to morbidity are quoted. In Michigan it has been found that most sickness is caused by rheumatism and neuralgia. Dr. Baker suggests that one of the reasons for the greater frequency of intestinal diseases in the summer time may be the fact that the toxic substances which cause peripheral disturbances like rheumatism and neuralgia in colder weather, may, in warmer weather, be able to affect unfavorably only the somewhat irritated mucous membrane of the intestinal tract.

In the practical therapeutic referendum at the end of this volume, Dr. F. O. Thornton gives a series of prescriptions that are applicable to various conditions, the details of which have been given in various parts of the present and the preceding volumes of "Progressive Medicine." Most of them are either newer combinations of old remedies, or are favorite prescriptions of new remedies, which have been found most useful in late years. It is unfortunate that the Latin in this section was not reviewed with a little more care. The barbarism *fiant in chartulæ* occurs a number of times, and this is by no means the only one that may be noted even on cursory reading.

THERAPEUTIC HINTS.

Treatment of Pruritus by Salicylate of Methyl.—After successfully employing this remedy for the relief of pruritus, local and general, Leredde recommends the following pomade as the most serviceable means of application. Being of a thick consistency, it adheres closely to the skin. It is best adapted to the treatment of local pruritus and never causes irritation of the skin.

℞ Methyl. salicyl.....3 ss
Zinci oxid.
Vaselini.
M. Ft. unguentum. Sig. External use.

VOL. LXXVI. NEW YORK, SATURDAY, JANUARY 20, 1900. NO. 3.

ORIGINAL ARTICLES.

THE OPERATIVE TREATMENT OF MYOPIA OF HIGH DEGREE BY THE REMOVAL OF THE CRYSTALLINE LENS.[1]

BY CHARLES STEDMAN BULL, A.M., M.D.,
OF NEW YORK.

ONE of the scourges of modern civilization is myopia or near-sightedness. It may be regarded as one of the hereditary enemies of civilized man. Owing to its early development in childhood it may be considered a sort of social plague, for it reaches all ranks of life and limits the usefulness of the individual in all pursuits. It is a serious menace to modern education, and so widespread has it become that in the near future the condition of the eyes of our children will necessitate some decided modification in the standards for entrance into our higher schools and colleges. This is not the place for any detailed consideration of the subject of modern education, although it is entirely germane to the subject; but a brief plea may be made for an earlier and more careful examination of the eyes of school children, and for a stricter investigation into the whole subject of school hygiene, including the ventilation and lighting of school-rooms, the relative height of desk and seat, the arrangement of blackboards and charts for illustration, the length of the study-hour, and the frequency of intermissions from study.

The great danger of myopia lies in the progressive tendency of the disease in many young patients, and the question of operative interference has to do only with the progressive form of hereditary degeneration of the choroid and retina; a myopia complicated not only by progressive posterior staphyloma, but by the development of degenerative changes in the retina and choroid, whether predisposing or hereditary.

The disadvantages of high myopia are very great and are often positively inhibitory of any close work. Patients are rarely able to wear concave glasses stronger than D 12 or D 14, because such glasses make the retinal images of objects very small, and because of the distortion of these images by the lateral rays. Very myopic individuals cannot occupy themselves with any close work for any length of time, on account of the physical and ocular fatigue induced by bending over the work, and the continuous strain on the accommodation and conveyance. Various suggestions have been made by ophthalmologists in the past to overcome these difficulties. It was at one time supposed that the elongation of the optic axis in myopia was due solely to the pressure of the external ocular muscles on the eyeball, and hence tenotomy of the external recti muscles was advocated. Later Galezowski actually proposed to excise a crescentic piece from the cornea for the purpose of arresting the progress of the myopia.

The removal of the lens in high myopia was first proposed by Beer in 1817, who claimed that the condition of these myopic patients was much improved thereby; their vision was increased and their capacity for work improved, and they were protected from the dangers of increasing myopia. Beer, however, had no followers and nothing more was heard of the subject until 1858, when Mooren again advocated it. The operation was opposed by Von Graefe because it did not arrest the progress of the myopia, and by Donders who considered the removal of the transparent lens as a punishable offense. The operation again languished until Fukala took up the subject of the removal of the lens in 1887, and has continued to be the stanchest advocate of the operation. A very brief résumé of the work done during the last ten years naturally follows.

Fukala's first paper was published in 1890 and was based on nineteen cases, all of the patients under twenty-four years of age, who could read Jaeger No. 1 at the far point, and who showed no disease of the fundus. He first made a small discission of the anterior capsule and repeated this as often as necessary, trusting to the absorptive power of the eye to get rid of the soft lens matter. Subsequently he prefaced the discission by an iridectomy upward. He claimed the following advantages for the operation: (1) Distinctness of distant vision; (2) enlargement of the retinal images; (3) relief from the extreme strain of accommodation; (4) relief from the disadvantage of bending the head over the work; (5) restoration of binocular vision for the near-point. Fukala's next important paper on the subject was published in 1894. He did away with the preliminary iridectomy and advised an extensive laceration of the anterior capsule, and he removed the swollen lens as soon as possible through an incision in the cornea. He considered that young patients promised the best results, and was inclined to limit the operation to patients under forty. He found that the improvement in vision after removal of the lens was from two to five times greater than before the operation and sometimes surpassed this. In some cases there was an arrest in the progress of the myopia. He confirmed our ideas as to the cause of the progressive tendency, *viz.*, first, the

[1] Read before the New York State Medical Association at its Sixteenth Annual Meeting, held in New York, October 24, 25, and 26, 1899.

stretching of the ocular coats in consequence of congenital tendency, and, second, the unfavorable influence of the accommodation maintained so constantly in young myopes.

Fukala's third important paper appeared in 1897. In it he called attention to the fact that the acuity of vision of an eye depends on three factors: (1) The size of the retinal images; (2) the intensity of illumination of the latter; (3) the perceptive ability of the retina. In comparing the visual acuity with the size of the retinal images it should be remembered that the latter do not present lines but surfaces, and hence their superficial contents must be considered. He endorsed Schanz's investigations, who found that the loss of light caused by refraction and reflection is less in eyes from which the lens has been removed than in the eye with the lens in place, for the eye, by this operation, is reduced to the simplest optical apparatus, having but one refracting surface. This advantage is the more marked if the eye becomes emmetropic by the operation, needing no correcting lens. He considers that the improved sharpness of vision after extraction is due to: (1) The increased size of the retinal images; (2) increased intensity of illumination of the retina; (3) the optical apparatus is simplified and the lenticular reflexes are absent. He, therefore, claims the following advantages for the operation: (1) A varying amount of improved vision for distance, with considerable diminution of refraction: (2) central vision is improved from four to twelve times, caused by the advancement of the second nodal point producing an enlargement of the retinal images; (3) the operation does away with the strong convergence of the optic axes and with the inclination of the head forwards for near vision, both of which points are strong factors in the causation of increasing myopia. The patient after operation can read and work at a much greater distance from the object, and may even require convex glasses; (4) all accommodation is lost, which is one of the factors active in causing increase of the myopia; (5) if both eyes are highly myopic and of unequal visual power, the weaker eye develops strabismus divergens in consequence of the disturbed binocular visual act, and here the operation is particularly indicated and often restores the binocular visual act.

Since the publication of Fukala's first paper, other observers have taken up the subject, and in the years that have elapsed the number of operators has gradually increased and now includes some men of conservative position and established reputation. They have, however, been confined almost entirely to Germany and France. The advocates of the operation all claim the same advantages, as follows: The aphakial eye, or the eye deprived of its lens, becomes by the operation either very slightly myopic or else hypermetropic; the retinal images are larger; the eye has greater visual acuity; the far point recedes from the eye; excessive efforts at convergence and also the congestive phenomena disappear.

Vacher, the most active advocate of the operation among French ophthalmologists, at first advised it only in those cases in which the visual condition prevented the patients from working, and only in eyes with more than D 14 of myopia. Where the myopia was more than D 18, he advised operating on both eyes. He at first claimed a satisfactory result in every case, although the visual acuity was not markedly improved. As his experience increased, however, he grew more enthusiastic and he has become venturesome to an inexcusable degree. He now advises extraction of the transparent lens, without either discission or iridectomy. He regards the operation as a phophylactic against both increase of the myopia and detachment of the retina. He operates on one eye only from preference; and if the patient has only one useful eye, he does not operate. He considers that neither choroidal degeneration nor extreme age of the patient is a contraindication.

Schweigger, a very conservative observer, also favors the operation in cases of more than D 16. He does first a discission of the anterior capsule, and then extracts without an iridectomy, which he considers entirely unnecessary. He makes the corneal incision downward, 2 mm. above the corneal margin, extracts the nucleus and as much soft lens substance as possible, and whatever lens matter remains behind may safely be left to absorption. He does not think that the acuity of vision is much increased by the operation. Pflueger corroborates all the advantages claimed by Fukala. He does not favor extraction of a senile lens in high myopia. He recommends laceration of the anterior capsule with Bowman's stop-needle, with or without iridectomy, according to the age of the patient. Extraction should follow within a week after the discission. Extensive degeneration of the choroid in the region of the macula and great age of the patient both contraindicate the operation. The younger the patient the better the prospects. One eye should be operated on at a time, and if the swelling of the lens be marked, extraction should be done at once.

Schroeder draws the following conclusions from his somewhat large experience: (1) The danger of the operation in otherwise normal myopic eyes is trifling; (2) even with chororetinal changes in the fundus, a retinal hemorrhage is only to be feared when the changes are at the macula; (3) the changes in the eye caused by the operation do not increase the dangers to which such eyes are subject, such as detachment of the retina and choroiditis; (4) a lessening of these dangers by hindering the increase of the myopia and the development of choroiditis has not been proved. Von Hippel, another conservative observer, prefers to operate on both eyes if both are highly myopic. He does not regard choroidal degeneration as a contraindication. He lacerates the anterior capsule and goes deep into the lens, but takes care not to wound the posterior capsule, so as to avoid prolapse of the vitreous.

He considers iridectomy unnecessary, and never operates on myopia less than D 12. Lagleyze believes that extraction of the lens is indicated in all cases of progressive myopia over D 14. He makes a discission and then a simple linear extraction in the cornea. He operates on both eyes if identical conditions exist in both eyes. Choroidal changes are not a contraindication unless the macula region is deeply involved.

Wray's views are not entirely favorable. Three objects are to be attained by the operation: (1) To enable the patient to work easily at the reading distance; (2) to arrest or prevent degenerative changes in the retina and choroid; (3) to prevent a detachment of the retina. He considers that detachment of the retina is a comparatively frequent mishap after the operation. The latter is to be regarded as a success if it prevents progressive degenerative changes in the fundus and enables the patient to work. Floating opacities in the vitreous and diminished tension would contraindicate the operation. Hess is one of the more radical advocates of the operation. He makes a corneal incision upward with the narrow knife and lacerates the anterior capsule at the same time. He then immediately extracts the lens. Frohlich is not a partisan of the operation, because of a number of secondary complications, *viz.*, (1) After discission there may be incarceration of the sphincter margin of the iris in the wound; (2) after linear extraction there is apt to be incarceration of the periphery of the iris and of the lens capsule in the corneal wound; (3) detachment of the retina after secondary operations.

Swanzy is an advocate of the operation in proper cases. He advises a simple discission without extraction, this to be repeated as often as may be necessary as the method the least likely to be followed by detachment of the retina or intraocular hemorrhage. It is not to be recommended except in myopia of D 10 or over, nor in any case where serious lesions of the fundus or vitreous exist. The best period of life is childhood or youth. The advantages to be gained are enormous, while the risks are slight. The acuteness of vision is usually markedly increased and goes on improving for several months before reaching the maximum. Panas draws the following conclusions based on about five hundred operations. In high progressive myopia above D 16 the operation is perfectly justified, provided the visual acuity is sufficient and provided there are no macular lesions and no amblyopia from strabismus or other cause. The younger the patient, the more favorable for the operation. Discission of the anterior capsule followed by simple linear extraction without iridectomy is the best method for young subjects. In adults it is better to do an iridectomy. Atrophic choroidal lesions do not contraindicate the operation, unless they involve the macula or are accompanied by detachment of the retina.

Otto recommends first extensive laceration of the anterior capsule with a sickle-needle. Atropin is then instilled, the eye is bandaged for forty-eight hours, and the patient carefully watched. The iris is kept dilated and there is generally little or no reaction. The swelling of the lens goes on rapidly or slowly according to the age of the individual. If severe pain and tension come on warm compresses should be used, but if the symptoms continue the lens should be extracted. He extracts by means of a bent lance-knife, the wound being made upward in clear cornea, the lens matter being removed by pressure and counter-pressure. He never uses a spoon. Iridectomy may be avoided in most cases. In children, discission alone generally suffices.

Sattler, another conservative operator, bases his conclusions on ninety-five cases. In no case was the myopia under D 12, and most of them varied between D 18 and D 24. Iridectomy was not done in any case. He uses a hollow lance-knife, makes the wound from 1½ to 2 mm. from the upper corneal margin, and 6 to 8 mm. long. He opens the capsule horizontally with a sharp hook, and then passes the hook within the capsule with its back towards the equator of the lens and posterior capsule, so as to loosen the entire lens substance. He then by pressure and counter-pressure removes all the soft lens matter possible. The iris is then replaced. There is very little reaction, and the patients are sent home on the seventh day. He claims that by this method of operating the period of healing is shortened, there is no reaction or irritation, and the resulting astigmatism is trifling and transient.

Hess, Hirschberg and Von Hippel endorse this extraction without needling and without iridectomy. Jessop believes that in children and young adults, with high, uncomplicated myopia, the operation should be undertaken because of the great advantages to be gained. Jackson holds that it is not proper to resort to operation in any case where the progress of the myopia can be arrested by wearing correcting lenses and ordinary hygienic precautions.

Knapp does not approve of removing a transparent lens, for, owing to some of the cortex remaining behind, the results will be unsatisfactory from suppuration, or iridocyclitis, or intraocular hemorrhage, or detachment of the retina. He thinks that the real value of this treatment of myopia will be recognized when the period of its boom is passed.

This brief résumé of the more important literature of the subject has shown that some of the most careful and conservative authorities have become advocates of the operation in selected cases and under certain wise restrictions.

The optical effect of the removal of the lens upon the refraction of the eye is a matter of scientific interest, and in axial myopia may be calculated with sufficient exactness by means of a formula, having first measured the radius of the corneal curvature. The optical results obtained by aid of the extraction of the lens in these cases confirm the generally admitted fact that the great majority of these cases are due to an elongation of the optic axis. The opinion that the lens plays

an important part in causing high myopia and that it has a greater refractive power than the lens in emmetropia is proved to be erroneous. The amount of reduction in the refraction of an eye by the operation is much greater than would be expected, and is estimated by Ostwalt as averaging D 16. The ideal effect to be gained from the removal of the lens would be a post-operative myopia of D 2 or D 3 in which no glass is needed for near work, and even the distant vision is better without glasses than before the operation with strong concave glasses. If a condition of emmetropia results from the operation, the patient will require a moderate convex glass for near work.

My own experience in operating on cases of high myopia has been extremely limited and the number of cases is too small from which to draw any conclusions as to the advantages or disadvantages of the operation. But a careful review of the really important publications on the subject, in addition to my own limited experience, may justify perhaps the presentation of some theoretical conclusions.

Before all is it important to carefully examine and study your cases, before deciding on a serious operation, which is accompanied by the possible occurrence of grave dangers. The actual existing condition of the myopic eye with reference to its seeing power should be definitely settled, and also the fact whether the degree of the myopia has recently increased and to what degree. The age and occupation of the patient and the necessary demands made upon the use of the eyes should be considered. The possible subjective annoyance caused by the wearing of correcting glasses should be noted. A careful ophthalmoscopic examination of the fundus should be made under atropin mydriasis, with special reference to the condition of the blood-vessels of the retina and choroid, particularly in the equatorial region. The meridians of greatest and lowest refraction should be determined by the ophthalmometer likewise under atropine mydriasis. A careful examination should be made of the visual field by the perimeter. Finally, the tension of the eye should be accurately tested. The intra-ocular tension of a highly myopic eye is apt to be above the normal standard, and a minus tension would cause suspicion of serious disease of the fundus.

The possible *dangers* from the operation are four in number and are in the order of their importance and frequency as follows: (1) Intra-ocular hemorrhage from rupture of a choroidal or retinal vessel; (2) detachment of the retina, with or without hemorrhage; (3) secondary glaucomatous symptoms, such as increased tension, ciliary injection and pain, all resulting from the swelling of the lens after laceration of the capsule; (4) infection of the corneal wound or iris, or both. The third danger need not give uneasiness, as the symptoms of increased tension subside immediately on the extraction of the swollen lens. The danger from infection of the wound has been reduced to a minimum by modern antiseptic surgery, and almost never occurs.

A possible complication of the operation is an anterior synechia by adhesion of the iris to the cornea at the point of entrance of the needle in discission, but this should never occur if the iris is kept dilated by atropin. Another possible complication after the extraction of the lens is an incarceration of the iris in the corneal wound or an actual prolapse of the iris through the wound. This latter is a rare occurrence and when it happens the prolapsed iris should be immediately excised.

The conditions which should contraindicate any operation may be enumerated as follows: (1) Extensive degenerative changes in the retina, and choroid in the region of the macula lutea; (2) detachment of the retina already existing; (3) membranous opacities in the vitreous, which indicate more or less extensive disease of the choroid and of the walls of the blood-vessels; (4) the previous loss of one eye from whatever cause; (5) decided loss of transparency of the cornea from previous inflammation; (6) any form of contagious conjunctivitis, particularly trachoma; (7) advanced age of the patient, and (8) a myopia of less than D 12.

Indications for the Operation.—The indications for the operation are given first by the degree of visual acuity actually existing at the time.

(1) If the central vision of the myopic patient with the best possible correction by glasses is not sufficient for the needs or social position of the patient, the operation is indicated, first on one eye and then on the other, if no contraindications exist.

(2) If there are unmistakable evidences of a rapid increase in the amount of near-sightedness, true progressive myopia, and if the myopia is D 12 or more, the operation may be done, of course, under the previously mentioned restrictions.

There seems to be no reasonable doubt that by the removal of the lens, the vision of all myopes is decidedly improved and this improvement continues for some months after the operation. The results seem to be equally good for all grades of myopia, and the success in complicated cases seems to be relatively as good as in the uncomplicated cases. The wearing of moderate convex glasses after the operation is much less annoying to the patient than the wearing of strong concave glasses before the operation. The age of the patient certainly does influence the duration of the healing process, but not necessarily the final effect of the operation. The description of the operation forms a fitting termination to the paper. In children it is better to employ general anesthesia, but in adults the operation may be performed under cocaine anesthesia. All the steps of the operation are done under the strictest aseptic precautions.

The patient's face is first washed with boiled water and aseptic soap, and then thoroughly cleansed with a solution of bichlorid of mercury (1-1000). Towels wrung out in the same solution are then placed around the patient's face and over the hair, until all is covered but the region of

the nose and the two eyes. The cornea having been rendered non-sensitive by cocaine, a speculum is introduced beneath the eyelids so as to keep them open. The conjunctiva over the inferior rectus tendon is then seized by a pair of forceps with blunt teeth and the eyeball is rotated gently downwards. A Bowman's needle or a very slender straight narrow knife is then passed through the cornea about 2 mm. from the outer margin and through the pupil, and a free laceration of the capsule either horizontally or vertically is made. If the patient is in middle life or over, a crucial laceration of the capsule should be made and the needle should also tear apart the superficial layers of the lens. Under no circumstance should the posterior lens capsule be wounded. The needle or knife should then be rapidly withdrawn, and an aseptic solution of atropin, two to four grains to the ounce, should be instilled. An aseptic bandage must then close the eye. This bandage should be removed the following morning and atropin again instilled in order to keep the iris widely dilated. If the lens becomes rapidly swollen by imbibition, the bandage is to be discarded and the eye kept under the influence of atropia and hot bathing until the symptoms of irritation subside. If the tension becomes rapidly increased and the symptoms of secondary glaucoma are imminent, the lens must be extracted at once. In the hands of a skillful operator, the narrow cataract knife is to be preferred to the lance knife. I make the incision upward in clear cornea, exactly as if for the simple extraction of a senile cataract, and about one millimetre from the sclerocorneal margin. Then by gentle pressure and counter-pressure the wound is made to gape and the soft cortex is pressed out through the wound. Usually the iris prolapses, but this need not interfere with the removal of the lens substance. By gentle manipulation the soft cortex is pressed out until nearly the entire lens mass is removed. The eye is then washed out with a warm saturated solution of boric acid, the prolapsed iris is replaced in the anterior chamber with a spatula and a drop or two of a ten per cent. solution of cocaine is instilled. The eye is then bandaged aseptically.

I prefer to do this operation while the patient is lying in his bed, thus avoiding all jarring by transportation. Unless the patient complains of severe pain, the bandage is not removed for forty-eight hours. It is then taken off, the eye carefully irrigated with a (1-5000) bichlorid solution, atropin instilled, and the eye is again bandaged for another period of two days. The bandage is then removed, the same irrigation and instillation repeated, and a mask is put over the eyes, nose and cheeks and tied around the head. Should the posterior capsule become opaque as it sometimes does, no attempt should be made to lacerate it until a period of three months has elapsed. It should then be cut through cleanly by a sharp, slender knife, and not torn through by a needle. In this way the danger of a subsequent cyclitis from traction is minimized.

GONORRHEA; ITS DANGERS TO SOCIETY.[1]

By ALBERT NEISSER, M.D.,
OF BRESLAU, GERMANY;
DIRECTOR OF THE ROYAL DERMATOLOGICAL HOSPITAL AT BRESLAU AND PROFESSOR OF DERMATOLOGY IN THE ROYAL UNIVERSITY OF BRESLAU.

(Continued from p. 45.)

WE have learned in the last few years that gonorrhea plays a very extensive rôle as one of the causes of arthritic rheumatism. It seems probable that this knowledge will lead to a change of opinion with reference to the cause of a large number of chronic cardiac complications which now are attributed to simple rheumatism. The matter is yet, however, *sub judice*.

A feature of gonorrhea of very special significance is the fact that its infectiousness may persist for a very long time in spite of seemingly successful treatment of the local affection of the genitalia. Men and women can for months and years be capable of infecting others although they have only very slight objective symptoms, and practically no subjective symptoms, and therefore with seeming good reason consider themselves entirely well. It is evident how pernicious are the consequences of this fact and how much seriousness it adds to investigation undertaken for the diagnosis and prophylaxis of the disease. Sexual passion tempts frivolous and conscienceless individuals unfortunately only too often to sexual intercourse in spite of a knowledge of their infectious disease. How can we hope to keep the unnumbered thousands of individuals who still have gonorrhea from spreading the disease through sexual congress when they practically know nothing and can know nothing of the fact that the disease has persisted?

The greatest triumph of the modern medical struggle with gonorrhea seems to me to be the fact that we can now by careful search for gonococci make clear the dangerousness of chronic gonorrhea. Conditions which were formerly considered to be practically harmless and which, so far as our worthless clinical investigations went, actually seemed so, we are now able, by the aid of our microscopic and bacteriologic investigations, to pronounce with certainty to be infectious.

This knowledge has also laid the foundation for a successful rational therapy of the disease. The indication is, cure an acute gonorrhea at once before it has succeeded in bringing about the serious and intractable complications and sequelæ which so often follow. This knowledge has made it clear to us, also, that in spite of objections and certain difficulties that attach to the method, if we are to trace out for prophylactic and hygienic reasons the existence of gonorrhea, especially in what regards the examination of prostitutes, we must call microscopic and bacteriologic science to aid us. Fortunately, the non-medical public is beginning to realize the importance of this knowledge of the significance of gonococci, and,

[1] An answer to the second question of the Conference for the Prophylaxis of Venereal Disease, held at Brussels, September, 1899. Translated by Dr. James J. Walsh for the MEDICAL NEWS. All rights reserved.

therefore, it is to be hoped that gradually the group of gonorrhea patients who most demand our sympathy, namely, the young married women who are infected by their husbands shortly after marriage, will gradually disappear. This eminently to be desired consummation will be reached all the sooner and surer when every physician is master of and habitually makes use of the technic for the microscopic diagnosis of gonococci.

The large number of young women who are thus infected by their husbands might well be classed as suffering from gonorrhea insontium. There is, however, another important class of innocent gonorrhea patients. Not infrequently gonorrhea occurs in children, as an epidemic, especially in little girls. A great majority of the cases, however, are due to chance contact with the gonorrheal virus either from sleeping with an infected person, such as a mother or sister, or by incidental contact with infected linen, or bathing with others. These cases of gonorrhea in children may be followed by exactly the same serious consequences, even including fatal peritonitis, as occur in cases of gonorrhea acquired from sexual intercouse in adult life.

What are the social losses, that is to say, damages to the well-being of society in general, which the large number of cases of gonorrhea brings about?

Although the general mortality is practically uninfluenced by gonorrheal affections, even though we include herein the endocarditis, peritonitis, and the deaths from operation which occur as sequelæ of the disease, certainly the morbidity of the population is increased in a very striking way. This means: (a) That there is an enormous loss of working strength and in workmen's wages, due to the confinement to bed, residence in hospitals, and the fact that many are compelled to give up their occupations for a time because of their gonorrheal affections. (b) The disease involves large private and public expense. Least harm is done when the disease affects single people who have only themselves to care for. A married woman, however, is very likely not to escape the fate of gonorrheal pelvic disease since because of the small earnings of her husband she is not able to permit herself to take a rest. Were it possible for her at the beginning of the disease, and especially just after her first labor, to take good care of herself for some time she would very probably escape without serious consequences.

The woman's social condition and that of the family, with the worry for daily bread, becomes then the occasion for illness which brings with it as a result further serious consequences Sickness of the wife means in the household of the workman and among the lower classes generally, not only a lessening of the earning power of the family, but also the lack of the only power which keeps the household in proper order and so looks out for the physical and moral welfare of the man. If the wife is sick and ailing, depressed and nervous, often confined to bed, or if she must spend weeks or months in a hospital, the temptation for the man to prefer the saloon to the unpleasant surroundings of his own home and the occasion which his absence from home provides for the satisfaction of sexual passion illegitimately are too alluring for us to expect that a great many men would not yield to them.

If the man become infected for the first time after marriage, this usually happens during his wife's puerperium. Now, should he afterward infect his wife at a time when perhaps there are several children in the family, the lessening of the earnings because of the illness of the man and also that of the woman will be even more keenly felt and the injury caused by neglect of the children will prove of even more serious importance. It is sad to realize that in such cases we are apt to think of it as a bit of good luck if the wife should become sterile as a result of the affection. It is the influence of this thought which eventually determines the performance of an operation. It is certainly not without danger, but it is readily accepted because of the condition of helplessness and incapacity for work which has developed in the woman.

This whole chain of miseries, with the sacrifice of time and money which it involves, is repeated thousands and thousands of times in families as a result of the gonorrhea of the husband. When we consider it, it is surely clear how false is the common opinion and, unfortunately, also the legal regulation in the matter (at least here in Germany, as regards the workman's aid society) which debars patients suffering with gonorrhea from being treated in hospitals as they should be. The first link in the chain would thus be broken and the man prevented from inflicting injury on himself as well as on others.

In practise just the opposite happens. Since the disease is considered a shameful one the patient does his utmost to hide it as far as possible. Instead of going at once to a physician, or into a hospital, he has recourse to any method of treatment which friends or charlatans may suggest. Often enough he has not the means wherewith to pay for hospital treatment and the principle that a sufferer from venereal disease has a right to free hospital treatment is unfortunately put into practise in but very few countries. The best that can be hoped from any method of treatment that the patient will have is that the cure of his disease will only be delayed. Very often, however, the exacerbations and complications which we have sketched above supervene. These soon necessitate a stay in the hospital or confinement to bed and probably for a rather long period.

From this lack of treatment result all the sequelæ and relapses which more or less cause frequent and serious attacks of illness in later life. The worst feature of these chronic gonorrheal affections is in innumerable cases the persistent infectiousness which the man (and the woman) carry with them into marriage. In addition to the second victim, who is usually entirely inno-

cent, there often comes a third, the child, which suffers from gonorrheal ophthalmia. (This is, of course, excluding for the moment all chance contagiousness of the disease for older children.)

If we are to look upon these venereal diseases as a punishment for illegitimate sexual congress, then it must be admitted that they are quite as much a punishment for the community as for the individual. They certainly prove a punishment for a very large number of absolutely innocent persons. To increase this so-called punishment by refusing to aid in every way possible those who are infected to get rid of the affection thoroughly, easily and conveniently, is to still further punish the community in which they reside.

It is very difficult to obtain an exact idea as to the extent of the mortality which results from operations for gonorrheal affections. Certain factors, such as the technic of the operator and aseptic and antiseptic methods of surgery, besides the variety of opinion with reference to the necessity for operation in these cases and the preference that some have expressed for conservative treatment, modifies very much any conclusion which might be drawn from the statistics that are at hand. It is difficult, moreover, to make the necessary separation between what are surely gonorrheal and non-gonorrheal affections of the uterine adnexa. Schauta lost 2 out of 33 positive gonorrheal affections on which he operated, that is 6 per cent. Of 134 probable gonorrheal affections operated on by other operators the mortality was 4, that is, 2.8 per cent. In operations for purulent salpingitis the death-rate was from 7 to 12 per cent; in the non-purulent form from 1.2 to 3.2 per cent.

A good idea of the loss of time and expense involved in the treatment of gonorrhea can be obtained from the number of days of treatment as recorded in hospitals.

For the various armies the following table gives these details:

	Duration of Treatment of Gonorrhea.					
	Total No. of Days of Treatment.			Average No. of Days of Treatment for each Patient.		
	1891-92	1892-93	1893-94	1891-92	1892-93	1893-94
German Army.....	213,694	232,112	245,073	29.4	30.9	29.3
Austrian "	329,400	318,126	318,168	36	37	36
Belgian "	24,824	23,920	33,830	27	26	34
French "	305,719	286,501	308,121	27	26	34

In Breslau in the year 1897-1898, out of 25,386 days of treatment for patients in the Royal Dermatological Clinic, 3465 were credited to 166 patients suffering from gonorrhea. In All Saints' Hospital, a municipal institution, the records gave 39,060 days of treatment in the Dermatological department during the year 1897. Of these 4175 were credited to 126 patients suffering exclusively from gonorrhea. These figures are relatively not large when taken by themselves; they obtain, however, a great significance if we bear in mind that the disease is due to direct contagion and that it is in a certain sense absolutely avoidable.

As far as prostitutes are concerned, the following figures are at hand for Breslau: In the year 1888, 193 individuals were treated for 6362 days. From July 1, 1889, to June 30, 1890, 193 persons were under treatment for 7336 days. In the year 1890, 211 persons for 6835 days. In the year 1891, 179 persons for 6994 days. The cost of treatment varied from thirty-five to sixty cents a day, so that the average yearly expense was 13,000 marks (about $3000). In the Vestre Hospital in Copenhagen the number of days of treatment for urethritis were as follows: In 1893, 30,704 days; in 1894, 34,788 days; in 1895, 30,410 days; in 1896, 36,883 days; in 1897, 23,893 days. The cost of such hospital treatment would be enormously increased if we were to institute a medical surveillance of prostitutes which were worth the while, and if inspection for gonorrhea were to be carried out with the detail necessary to prevent the escape of cases. To this end not only would the number of physicians have to be greatly increased, but the number of patients whom it would be necessary to treat would become very large.

We must make special mention here of the gonorrheal affection of the conjunctiva which frequently leads to unilateral and sometimes to total blindness. The affection is acquired during labor from an infected mother or in a case of adults by chance contact of gonorrheal pus with the conjunctival tissue. (In Egypt this gonorrhea of the eye is said to be very widely distributed even among adults. The contagion there, it seems, is usually carried by flies in the shape of purulent material, or even the gonococci themselves, from one individual to another.)

Even in our day, at least ten to twenty per cent. of all blindness is due to gonorrheal infection. In many institutions for the blind the number is even higher, as many as sixty per cent. of the inmates being blind from this cause. The number of such cases in the last fifteen years has become much smaller than formerly. The improvement in this matter is due to the introduction of the Credé method of instilling a 2 per cent solution of nitrate of silver in the eye immediately after birth. Before this method was employed the number of cases of gonorrheal ophthalmia that occurred in most obstetric institutions was 8 to 12 per cent. or even 14 per cent. of all births. And in every 100 cases of gonorrhea there were three to five cases of blindness, so that in some institutions as many as 6 to 12 per cent. of all the infants born became blind. In our time most of these institutions have not a single case of this form of infection to report. It is therefore very desirable that the Credé method should be employed after every confinement. It is extremely sad to think that in Germany, for instance, we have to-day some thirty thousand blind whose loss of sight is due to gonorrheal ophthalmia. They might have been saved their life-long misfortune by the employment of the Credé method. Besides the blind, however, it must be remembered that there are numbers of

individuals whose sight is very much injured by affections of the cornea. The number of such cases in many sets of statistics averages 28 per cent. of all the sufferers from gonorrheal ophthalmia. The extent of ophthalmia neonatorum gives also a very plain indication of the frequency of gonorrhea in the female. The significance of the successful employment of the Credé method goes far beyond its mere application to gonorrheal ophthalmia. The successful results here obtained show that it would be possible to successfully combat the causes of all other forms of gonorrheal infection. Just in the same way as we are able with assurance to prevent by Credé's method the occurrence of gonorrhea of the conjunctiva, we could also prevent urethral gonorrhea if the Credé method with proper regulations could be employed after all sexual congress.

The second, and from a social standpoint, very important factor, is the sterility which results from gonorrhea. To my mind it is clear that gonorrhea prevents increase in the population much more than syphilis, although it has been the custom to lay most of the blame upon the latter disease. There is scarcely a doubt left now that more than 50 per cent. of the involuntary childless marriages and limitation of the number of children is due to gonorrhea and its sequelæ in man and woman. As in most cases the man infects his wife, at least 45 per cent. of these cases are due to him.

As far as regards the direct cause of sterile marriages, it is now well known that in one-fourth of the cases the cause is gonorrheal epididymitis and the consequent *impotentia generandi* of the male. Besides it must be remembered that a certain number of men suffer from aspermatism. Others, as the result of inflammatory processes in the prostate, ejaculate into their bladders. Finally, a number have lost the potentia coeundi in consequence of gonorrhea or its complications.

The cause of sterility is explained when azoospermia, that is to say, absence of spermatozoa, can be demonstrated in the male. It was Kehrer of Heidelberg who first pointed out this cause for sterility in the male. He found it in 30 per cent. of all the marriages in which he was consulted with regard to sterility. Lier-Ascher confirmed these figures. Simmonds examined the testicles of 1000 bodies for the purpose of finding spermatozoa. He found them absent in 33 cases. All of these had venereal histories. In 22 cases the cause was gonorrhea. If we accept the ordinary figures that in 1000 marriages 10 per cent. are sterile, then these 22 cases of azoospermia caused by gonorrhea represent the percentage of sterility in the male in 100 marriages; that is to say, 22 per cent. of all cases of sterility is due to this cause. Among 600 husbands of sterile wives Fuerbringer found in 83.3 per cent. either absence of spermatozoa or suspicious infrequency of spermatozoa.

My own experience is not sufficient, although I have had a number of cases under observation to enable me to give any statistics that would throw light on the subject. I have found, however, in every instance in which men consulted me about the sterility of their marriages, that whenever impotentia coeundi was not the cause, spermatozoa were always absent. In practically every case the cause was double epididymitis. To my mind there is not the slightest doubt that the most frequent cause of absence of spermatozoa is gonorrheal epididymitis. Authorities in every part of the world, Busch, Fuerbringer, Giacomini, Godart, Gosselin, Liegois, Lier-Ascher, have stated that in all their cases of absence of spermatozoa there had been a preceding epididymitis.

Not only has double epididymitis and funiculitis been set down as the cause of absence of spermatozoa, but in a number of cases where these affections seem to occur only on one side they appear to act as causes of the same condition. Thus far, however, funiculitis has been neglected, although it presents just as much hindrance to the passage of semen as does epididymitis and it not infrequently happens that while an epididymitis is running its course on one side a funiculitis is being overlooked on the other side.

It must be conceded that even double epididymitis does not always cause absolute sterility. In 24 married men who had suffered from double epididymitis Benzler found absolute sterility in 10 only. In 5 of the marriages there was only a relative sterility, while in 9 the conditions were normal. Unless one would wish to question the character of all 14 of the women in these cases, one must admit that in nearly 60 per cent. of the cases procreative power remains in spite of epididymitis duplex.

In 87 married men with epididymitis on one side Benzler found absolute sterility in 16 only; relative sterility in 10; normal power in 71. The procreative power remained therefore in over 81 per cent. of the cases.

In contrast to this we may consider 363 marriages in which husbands had suffered from gonorrhea but had not had epididymitis. In 10 per cent. of these there was absolute sterility; in 17 per cent. relative sterility; in over 89 per cent. of the cases at least some procreative power. These last statistics correspond very closely to the percentage of sterility which obtains in all marriages.

Another series of investigators give the statistics of women who consulted them for sterility. Of most value are the investigations of Lier-Ascher, who found that out of 227 women 121 were sterile because of gonorrhea, and in 42 of the cases the women had been infected by their husbands. Besides these 79 wives suffering from gonorrhea there were 15 others who had been infected by their husbands, who, themselves, were suffering from gonorrheal aspermatism. In addition to these 42 men with azoospermatia there were 11 in whom spermatozoa were infrequent and impotency seemed to be the cause of the sterility. In a series of 197 relatively sterile women

gonorrhea was demonstrated in the husband only 35 times, although in 10 cases infection of the woman occurred during the puerperium.

Further statistics which show the relation of gonorrhea in the female to sterility are at hand. Noeggerath found among 81 women infected by gonorrhea 49 who were absolutely sterile. The remaining 32 women had borne only 39 children. Only one had as many as four children and only two had three children. Kehren found in 96 sterile marriages that 30 per cent. were due to absence of spermatozoa in the husband, while in 33 per cent. there were perimetritic exudations, in 8.3 per cent. amenorrhea, and in 4.1 per cent. vaginismus as a complication of the preceding gonorrhea. Kleinwaechter collected statistics of 648 sterile marriages. In 13 per cent. of these he found that gonorrhea in the female was the cause; this number is very small. There seems to have been a disporportionately large number of men affected by impotentia coeundi. Gruenwald, Kammerer and Chrobak report 53 per cent., 83 per cent. and 40 per cent. of endo-, meso-, and peri-metritis, all of gonorrheal origin, as causes of sterility in the female.

Williams insists that 73 per cent. of all abortions are due to endometritis of the cervix and body of the uterus.

I have not been able to give by any means an exhaustive idea of the severity of the affections which are due to gonorrhea. What I have said, however, taken in connection with the enormous distribution of the disease and its severe complications, must make every one feel that it is high time to sound a warning in the matter. Gonorrhea is a social danger for the people and requires the most careful attention from the authorities who are responsible for the public health. If we were able to do nothing to prevent the spread of gonorrhea, then, willy-nilly we should have to endure the evil. We now know, however, that the disease is always an infectious disease communicated from one person to another, and we can take measures to prevent its spread. No one is so optimistic as to believe that we shall ever be fortunate enough to get rid entirely of this serious popular plague. There can be no doubt, however, that by making use of all the means with which modern scientific medicine has supplied us we can lessen to a very large extent its ravages and can make its most serious consequences much milder.

It is not my purpose here to enter upon the ways and means by which this may be done. This is in fact the true task of the present conference. I cannot let pass the opportunity to compliment those who are mainly responsible for the conference on the fact that at length the occasion has come for the assembling of experts and authorities to discuss with proper publicity the problems connected with this important question. The first step in reform is for the public to know and to appreciate the dangers and the significance of venereal diseases. More effectual than all legal or police regulations will be the individual protection afforded by our present knowledge in this matter, if physicians and the laity will but realize our modern advances in this subject. I have not the slightest doubt that the present danger which threatens the human race from gonorrhea will be greatly lessened and the spread of the disease distinctly limited as the result of the discussion carried on here.

A VISIT TO THE NEWEST PSYCHOPATHIC HOSPITAL.[1]

BY FREDERICK PETERSON, M.D.,
OF NEW YORK;
PRESIDENT OF THE NEW YORK NEUROLOGICAL SOCIETY.

IT was as a student in the psychopathic hospitals of Strassburg and Vienna in 1881-1882 that the writer was awakened to the great need of similar establishments in the United States, hospitals for the insane in close connection with the buildings of our medical schools, where students could obtain some practical knowledge of a branch of medicine which is certainly of much importance to the general practitioner to whom all of our cases of insanity come in the earliest and most curable stages. I had hoped long ere this to see such psychiatric clinics founded in our medical schools, as clinical adjuncts to chairs of psychiatry (which, alas, are still wanting). Whenever possible I have lifted my voice and wielded my pen to further this cause. In the *Medical Analectic and Epitome*, January, 1890, I buried my earliest written communication on the subject of psychopathic hospitals. This was at a time when London was carefully considering the advisability of a similar project, which missed fruition, I believe, because of political exigencies. I was eager that New York should be the first to build a city hospital for the care of the acutely insane. Hence I wrote:

"The great demand for psychopathic hospitals . . . is to be met in one place at least—London—and it is time that New York was waking up to the extreme necessities of her own insane. Bloomingdale, which has received hitherto the richer classes of insane, is about to be removed to some distance from the city. The islands are inadequate in accommodation to meet the requirements of these unfortunates. A psychopathic hospital in the heart of the city, and in the neighborhood of Central Park, say on Eighth avenue, to receive those requiring immediate care and the highest medical skill, is the prime necessity of the hour. Let the city or some private individual subsidize or endow it!"

In my inaugural address[2] as president of the New York Neurological Society, delivered May 3rd, 1898, I again brought forward the idea of the psychopathic hospital as follows:

"Ever since I observed the splendid facilities for study in some of the foreign psychiatric clinics, it has seemed to me a misfortune that not one

[1] Read before the Northwestern Medical and Surgical Society of New York, October, 1899.
[2] "New Paths in Psychiatry," Phil. Med. Jour., June 11, 1898.

of our large cities on this side of the water is provided with such a center for psychologic investigation.

"Surely this great city, blessed with so many hospitals, charities and institutions of learning, possessed of so many citizens eager to employ their large wealth for benevolent purposes and for human progress, might well lead the cities of the new world in the establishment of a psychopathic hospital, a psychiatric clinic, fully equipped with all adjuncts for clinical, chemical, psychologic and pathologic investigation. A psychopathic hospital would accomplish great practical good. It would be a boon to the many insane now gathered daily into a pavilion at one of our hospitals merely for distribution to various asylums. In such a hospital many cases could be treated and cured, thus avoiding transfer and commitment to asylums. Medical students and special students of psychiatry would profit from the convenience of access to the psychiatric clinics and the young graduate would enter upon practise with some definite knowledge of insanity and its treatment. But the greatest value of the proposed special hospital would undoubtedly be the opportunities afforded for those aggregate studies by many specialists which are destined one day to discover the origin and cure of several of the psychoses, and incidentally to unravel some of the mysteries of mind."

In May, 1899,[1] I had the honor to deliver the annual address before the American Medico-Psychological Association, and in this, again, I made a point of bringing the psychopathic hospital before that distinguished body in the following words:

"It has long been an axiom among asylum physicians that early diagnosis and speedy removal to a special hospital for the insane are of paramount importance in nearly all acute psychoses. There are very few acute cases that cannot be more successfully treated in suitable special hospitals than in their own homes. Early diagnosis, if it means anything, means the diffusion of a practical knowledge of psychiatry among general practitioners. Now this object can be attained only through the establishment of psychiatric clinics in all of our larger cities, and especially in connection with medical schools. Clinical instruction in insanity is given as yet in but few of our medical colleges, and even where it now forms a part of the curriculum, it is given in a perfunctory way, the chair of psychiatry being generally combined with that of neurology, rather to the neglect of the former. Speedy removal to a special hospital necessitates ease of access, the least possible legal interference, and location in the centers of population. In fact, the same laws which govern the selection of sites for general hospitals are as appropriate for individuals sick from brain diseases as for those sick from lung, liver, or any other disease."

Indeed, why are they not more appropriate, if the relative importance of the diseased organ to life and happiness be considered? We should never dream of placing a general hospital for acute disorders in some remote region of the country. Why deal differently with acute disorders of the brain. Furthermore, one center of population in the commonwealth is no more entitled to benefit from the public treasury than another, so that the logical conclusion is that within the limits of each city of fifty thousand to one hundred thousand inhabitants there should be created by the State a special hospital for the reception and treatment of acute cases of insanity. Possibly isolated pavilions in connection with general hospitals might suffice for the needs of the smaller cities. Such hospitals for acute psychoses may be known as hospitals for nervous diseases, hospitals for mental diseases, hospitals for nervous and mental diseases, or, more briefly, following a recent suggestion, as psychiatric clinics or psychopathic hospitals. But the matter is of greater moment than the name. Since the acutely insane are ordinarily restricted, much as general hospital patients are, to their beds, wards, or rooms, location in the midst of a city is no greater disadvantage to the special than to the general hospital.

The law should be as lenient to this afflicted class of patients as is compatible with due regard to the preservation of their personal rights, never, however, for a moment forgetting that after all it is a sick man and not a delinquent with whom it has to deal. In the framing of laws for the commitment of the insane, delinquency has often quite eclipsed illness in the eyes of legislators. For our psychopathic hospitals, doubtless some emergency provision of ten days or more would be permitted before resorting to commitment by any legal process.

It seems to me, then, that the true method of dealing with the acutely insane consists in the creation of these special hospitals in all of our large cities. The more one examines the matter, the more convinced one becomes of the feasibility, economy, reasonableness, and humanity of such a course. It is the logical deduction from your axiom above referred to—early diagnosis and speedy removal to a hospital for the insane—and I venture to prophesy that before twenty years of our new century have passed there will be psychopathic hospitals in many of our American cities where now there exists not a single one. With the organization of such psychiatric centers, certain other important results will be attained. The profession as a whole will become more interested in, and more familiar with, the psychoses, owing to better facilities for study and observation. The chair of psychiatry in our medical colleges will become distinct from that of neurology. The city psychopathic hospital will gather to it all those spirits that are eager for discovery in the wide domains of physiology, psychology, pathology and chemistry in their relation to the central nervous system, for it is in the cities that most of these pathfinders reside, and

[1] "Some of the Problems of the Alienist," Med. Record, June 3, 1899.

only in the cities that collective investigations by various laboratories become possible. Attached to the hospital for mental disorders, in order to supplement the methodical clinical studies there made, there will be a variety of laboratories wherein the biologic unit of man may be studied by an aggregation of specialists trained in many branches of scientific work. Only in this wise will great discoveries and far-reaching results become attainable. There are good psychological laboratories now connected with a number of our universities, an outcome of the lively interest taken in recent years in the comparatively new field of physiological psychology; but their true sphere of usefulness and activity lies in combination with clinics and hospitals for nervous and mental disease.

"Not the least valuable feature of the psychopathic hospital with its laboratory annexes, will be an outdoor department or dispensary, to which will come not inconsiderable numbers of patients on the border-line of insanity, for still earlier treatment than the city insane hospital affords. Preventive medicine as regards disorders of the brain has never had such opportunity as will here be given to test the value of its methods."

While the psychiatric clinic or psychopathic hospital is an unknown institution in this country and in England and France, it is not a novelty, not a new and untried scheme, which we are asked to inaugurate. For more than twenty years it has been a success in Germany, and not as a solitary example, but in many towns and cities. There is but one university town in Germany which still lacks a psychopathic hospital, *viz.*, Kiel, and I had the pleasure this summer of looking over the plans of the psychiatric clinic which is about to be erected there. The Kiel clinic is to be built upon the model of the one at Halle. Thus two years hence there will be no university town in Germany lacking such an institution.

In August last I studied under the guidance of Prof. Kraepelin the system in vogue at Heidelberg, where there has been a psychopathic hospital in the midst of the city, adjacent to the other University hospitals, for some twenty years. This is now somewhat antiquated in point of construction, but there are over one hundred beds, and the clinical work of Kraepelin, the pathological work of Nissl and the psychological work of Aschaffenberg, testify to the value and importance of such a nucleus for the advancement of science in the domain of morbid psychology.

But now I approach the main object of this paper, *viz.*, a brief description of the newest psychopathic hospital in the world, which I visited this summer at Giessen (about an hour from Frankfort-on-Main). In the absence of Prof. Sommer, the director, I was indebted to Dr. Danneman, the senior assistant physician, and to Dr. Alber, the pathologist, for the opportunity of inspecting the design of the hospital and observing the methods of clinical investigation and psychological chemical and pathological study of the large material collected there. Giessen is a small town (some 15,000 inhabitants), the capital of the province of Upper Hesse. The University was founded in 1607. It possesses a large library, anatomical theater, observatory, botanic garden, chemical laboratory, museum of natural history, general hospital, infirmary, maternity, eye and other special hospitals, all situated in the midst of the town. Across the street from the general hospital and pathological institute (so near as to share in the lighting from a central electric plant) lies the group of eleven cottages which constitutes the *Psychiatrische Klinik zu Giessen.*

This clinical facility or convenience of access is of great advantage to the students of the University, since the observation of patients is not simply limited to the demonstration of cases at the clinical lecture, but they may be summoned quickly to witness transitory nervous and mental states, such as unusual phases of insanity, crises in general paresis, epileptic obsessions, and the like, as well as have the advantage of access to the wards at any time for the purpose of closer study of the patients. The eleven cottages which make the hospital are grouped together in a pleasant garden, and from the elevated position of all of the University buildings a fine view is presented in every direction, over the Lahn valley with its ruined castles and the wide expanse of rolling hills.

Aside from the residence of the superintendent or director and the kitchen building and administration building, there are four cottages for each sex on either side of the central structures. These four cottages or villas are thus divided: One for excited, one for restless and suicidal, one for quiet cases, and one for private patients. All of the buildings are heated from the kitchen building. The food is conveyed in suitable vessels in a cart constructed for the purpose from the central kitchen to each of the cottages. The electric lighting is derived from the general hospital plant. Something less than one hundred patients are accommodated. The overflow goes to the large country asylum in the province. The windows are nowhere guarded save in the cottages for violent and destructive patients. All of the modern conveniences and comforts are provided for in each structure. In each of the buildings marked "for restless and suicidal cases" is a clinical examination room, provided with every requisite for a thorough study of the patients, including clinical and laboratory instruments and apparatus of all kinds. The hydrotherapeutic and electrical apparatus for treatment are of the best. But while the means and methods of treatment are unexcelled, the most interesting features to the visiting physician are to be found in the central building. In this is a Policlinic for neuropsychic patients who come to the out-door dispensary for examination and treatment. It is needless to say that mental cases are seen and recognized here in the very earliest stages, and if hospital care is indicated it can at once be in-

stituted by the physician-in-charge. There is a waiting room for the patients next to the examination rooms. These latter are provided with electrical apparatus and instruments for the investigation of the blood, sensory-motor conditions, the eye, etc. Here are also cephalometrical apparatus, and the instrument devised by Prof. Sommer for studying the reflexes, and called by him the "reflex-multiplicator."

Adjacent to the Policlinic is the scientific library which is in every way adequate to the work in hand, and on the same ground floor is the suite of pathological laboratories in which every facility for autopsy and microscopical work is enjoyed. All of the rooms just described occupy the first floor of the right wing of the central building. On the same floor in the left wing are the administration offices and apartments for assistant physicians. The entire second floor of the administration building, including both wings, is given up to scientific purposes. The hallway is a museum of pictures, diagrams and plans relating to practical psychiatry, and contains also cases of valuable photographs and a large collection of skulls. The lecture-room or amphitheater has seats and desks for fifty students. The walls are covered with anatomical charts of the nervous system, and there are cabinets for microscopic specimens, photographic negatives and phonograph cylinders. There is a Zeis apparatus for the projection of microscopic sections on a screen and also for use in microphotography. The amphitheater is in the middle of the building, and to the left are the mechanical workshop, where all sorts of apparatus for the various laboratories can be manufactured, and the psychophysical laboratory. The latter consists of three rooms fully equipped with the electrical apparatus required for this difficult work, the complex instruments for a study of reactions, a Hipp chromoscope, and, in fact, a full assortment of all the mechanical devices needed for the investigation of the relations between mind and body. To the right of the auditorium are the laboratories for microscopical work and for physiological and pathological chemistry, and a room for photographic work.

I will not occupy your time with further details. My object in describing this institution as fully as I have done is merely to place before the profession a picture of a model psychopathic hospital to show the need of such addition to our teaching foundations and to aid in hastening the coming of that day when the acutely insane shall have equal advantages with patients suffering from other maladies for early diagnosis, immediate attention, and skilled treatment.

Yellow Fever.—Eighteen new cases of yellow fever and three deaths were reported at Havana during the first week in January. This indicates a decided increase in the number of cases, but diminution in mortality. The health authorities have decided to renovate again the infected districts.

DIURETICS IN RENAL DROPSY: THEIR INDICATIONS AND USES.

BY E. R. AXTELL, M.D.,
OF DENVER, COLORADO.

A STRIKING symptom of that peculiar complex of symptoms which we call Bright's disease is dropsy. It is a symptom that the patient usually notices and calls attention to. It is by no means present in every case of renal disease. It is usually present in acute nephritis, but we have all seen cases where it was very slight or absent. Where acute nephritis complicates pneumonia, typhoid fever or diphtheria, it is usually absent. In the form of subacute nephritis, and in that form where the kidney is large and white, dropsy is very common, being absent in only eight or ten per cent. In the interstitial form dropsy is much less common. In the early stages of the form it is generally absent, in fact almost never occurs, but later on it may appear as a result usually of cardiac failure.

Dropsy is simply a name for an accumulation of watery fluid in the lymph spaces of the subcutaneous cellular tissue and in the serous cavities of the body. This watery fluid is lymph and is derived from the capillaries. Under normal circumstances it is poured out into these spaces, but as fast as it is poured out it is taken up by the venous and lymphatic radicles. There are two essential factors necessary for the production of dropsy, and they do not seem to have an absolute relation to the condition of the kidneys. First, there must be an increase in the outflow of fluid; or, second, there must exist a failure on the part of the veins and lymphatics to take up the effused fluid.

It is not my province to enter into the physiological facts and experiments which have been made in this line. I think our present knowledge of the pathology of dropsy can be embraced in the following summary, which is modified from Saundby:

1. Dropsy is an accumulation of lymph or watery fluid in the lymph spaces of the body and serous sacs as a consequence of (*a*) defective arrangements, on account of which fluid accumulates; (*b*) changes in the blood and capillaries by which the outflow of fluid is increased.

2. Dropsy is present in most cases of acute and subacute nephritis. It is present in only about ten per cent. of the cases of uncomplicated contracted kidney. In the late stages of this disease it is more frequent, being present in twenty-five per cent.

3. In uncomplicated contracted kidney dropsy is due to heart failure; but in acute nephritis and its sequelæ it is due to more obscure causes in which a watery state of the blood is accompanied by increased permeability of the capillaries, caused possibly by the presence of an acid or other toxic substance in the blood.

This introduction is to serve for the very limited field which I have taken for this paper. In the treatment of dropsy we do not confine ourselves to diuretics—medicines which increase the

secretion of the urine—we also use diaphoretics and hydragogue cathartics; but I am not to consider in this paper the treatment of dropsy, but simply the use of diuretics in this condition. We all use diuretics at some time or another in the treatment of dropsy. I believe much harm may come from their use unless they are judiciously chosen. Diuretics may be divided into two classes; the direct and the indirect. To the first class belong all medicines which produce an increase of diuresis by influencing the kidney tissue directly. To the second class belong all medicines which produce an increase of diuresis by augmenting the general blood-pressure. This means, of course, an action on the heart, by which its energy is increased. Diuretics of this class do not act on the kidneys. They are incapable of augmenting the flow of urine when they fail to increase the force of the heart's action. When given to a healthy man or woman they do not markedly augment the quantity of the urine, simply because the blood-pressure is generally at its maximum height. Given, however, in a case where there is insufficient heart action and a small flow of urine, they often produce copious diuresis in a short time.

We could consider in elaborate detail the question of urinary secretion, but it is not necessary in an elementary paper, as this professes to be. We know a few fundamental facts with reference to the influence of diuretics on the kidneys. Any medicine which increases the flow of urine by a direct action on the kidneys, causes a more or less active hyperemia, with increased activity on the part of the renal epithelium. Some of the direct diuretics, when given in large doses, so augment the hyperemia that they render the urine bloody and albuminous.

For practical purposes the direct diuretics are divided into two classes, the saline diuretics and the stimulant diuretics. The salines take their names from the fact that they change the reaction of the urine, rendering it less acid or even alkaline; while the irritant or stimulant diuretics, when administered in excessive doses, diminish the quantity of urne and produce symptoms which show renal irritation or inflammation. The saline diuretics are those mostly used and recommended in the dropsy of acute nephritis.

The acetate of potassium, the citrate of potassium, the bitartrate of potassium, or the salts of sodium, lithium, calcium or magnesium, are all used. It is recognized now that the salts of potassium cause a more decided diuresis than the other salts mentioned, and they are preferred when an increase in the amount of urine is demanded. The acetate, citrate and bitartrate of potassium seems to possess equal diuretic power. This is probably due to the fact that before reaching the kidney they are converted into carbonates and eliminated as such. These salts in their elimination excite the renal epithelium, producing active hyperemia with an increased flow of urine.

In renal dropsy the saline diuretics are frequently used, and apparently without discretion. They may be useful, but they may be very harmful. In the dropsy of an acute nephritis saline diuretics do harm as long as the inflammation of the kidney is the cause of the diminished secretion of the urine. An inflamed kidney should not have its epithelium stimulated to increased activity; an artificial hyperemia should not be added to acute congestion. So harmful may saline diuretics be in acute nephritis that they may hasten the appearance of uremic symptoms.

I contend that all diuretics should be withheld in acute nephritis until the acute inflammation has subsided. This means that a period of one or two weeks ought to elapse before they are given. When the inflammation has subsided and there exists a scanty flow of urine, due to the presence of tube-casts and masses of blood in the uriniferous tubules, it will do more harm if they are not removed. On the passing of more urine, the dropsy often goes away slowly and steadily. In the dropsy of chronic renal disease I have never seen the saline diuretics do much good. They may increase diuresis, but they do not lessen dropsy. Certainly in any case of chronic reral dropsy one would not be justified in using the saline diuretics for any length of time. If the damaged kidney cannot secrete water, it cannot eliminate these medicines. In this way we could do harm.

The stimulant diuretics are frequently recommended in the most careless manner for renal dropsy. Take up almost any text-book and the list of diuretics to use is very great, and this without any apparent reference to whether harm can or cannot result from their use. It is true that in many cases of dropsy we get to a place where the question is, what is next? and where one sees the great need of a drug that will make the remaining kidney tissue do its work actively. It is in such cases that we are privileged to use renal diuretics, but not until diaphoretics and hydrogogue cathartics have been tried. That is the fundamental consideration. I mention here the usual drugs recommended for this condition; it is my intention to consider each briefly: Scoparius, squill, caffeine, pilocarpine, digitalis, diuretin, sweet spirits of nitre and calomel.

Scoparius is a stimulant or irritant diuretic and occupies a high place among the active diuretics of English physicians. It is recommended for renal dropsy in several American text-books. It can be used late in any renal dropsy. It decidedly augments the urinary secretion and sometimes the action of the bowels. It is employed in the form of a decoction, containing one part in twenty. Of this concoction the dose for an adult is two ounces every three to six hours. It is frequently combined with squill.

Squill is generally conceded to be contraindicated in acute nephritis and all forms of Bright's disease. It is, however, a diuretic of some power, and is classed among the indirect diuretics, it having been shown that its diuretic action takes place in consequence of a modification of the heart's action. Late investigations have shown that toxic

doses produce in animals no marked changes in the kidneys. Although squill is such a diuretic in renal dropsy it seems to have but little influence. I cannot, from personal experience, recommend its use in renal dropsy.

Caffeine citrate was first recommended for renal dropsy by Professor Gubler, who asserted that it was a powerful diuretic. His claim has been confirmed clinically many times. It is not to be used in acute Bright's, but can be used in chronic Bright's in doses of three grains every three to five hours. It apparently has a direct diuretic influence in addition to its cardiac action. Caffeine, when injected into the blood, affects blood-pressure but little. It causes dilatation of the renal vessels after a passing constriction and an increase in the flow of urine after a temporary diminution. It is often uncertain in its action. It will work nicely one time, and be of no service at another. It is worth a trial when other things have failed.

Pilocarpine hydrochlorate is nowhere classed as a diuretic, but some recent experiments of H. C. Wood indicate that it stimulates the kidneys. He says: "There is some clinical experience in favor of the plan of giving pilocarpine in doses of 1-10 of a grain three times a day, in order to avoid any violent action on the skin and get a decided increase of the urine."

Digitalis has, in the opinion of H. C. Wood, direct diuretic properties. He says: "The diuresis of digitalis is not simply a result of its action on the circulation, since it will sometimes appear before the circulation is sensibly affected. At the same time, it is very evident that in disease the good effect of digitalis upon the renal organs is often in large measure due to its action on the heart, but it is of value as a direct diuretic in renal dropsy both in the subacute and the chronic form, and while it frequently fails in these varieties of Bright's disease, yet it should always be tried." It may be given as fluid extract, tincture or infusion. The dose of the fluid extract is one, two or three minims every two or three hours, according to the urgency of the case or to the readiness with which the patient responds to the drug. This is always a variable factor. The tincture can be given in from ten to thirty minim doses every two or three hours. The official infusion, in doses of from one to three teaspoonfuls, is perhaps the best and most efficient form in which the drug can be administered, but it is at the same time the most trying to the stomach. Indeed, this drug in any form is apt to nauseate, and where we have this symptom present from a toxemia we are often deprived of the use of this valuable drug. Digitalin has not in my hands given me the results that I get with the infusion.

Diuretin was the name given by Dr. Christian Gram, of Copenhagen, to the salicylate of theobromine and sodium which he introduced as a substitute for caffeine. Extensive clinical experiments with the drug showed its diuretic action. It is a white powder, with a slightly bitter and disagreeable taste, and is very soluble. Its solution is very unstable and decomposes rapidly. This drug exerts its diuretic properties by a direct action on the secreting tissue of the kidneys. It acts promptly and energetically. Its effect is continued for twenty-four or thirty hours after administration. It increases both the solids and fluids of the urine. In all forms of dropsy due to renal disease, where a diuretic is demanded, diuretin can be used. There is certainly but little irritation to the renal epithelium, and very few bad results have been reported from its use. It may occasionally produce slight intestinal irritation and it has been known to cause slight delirium, but it is probable that in these cases the dosage was unnecessarily large. The best method of giving the drug is in ten to twelve grain doses, three times a day, to be increased to thirty grain doses if necessary. It is best administered in water with some aromatic essence, like essence of peppermint, to disguise its bitter taste, and always when the acidity of the stomach is at a minimum, *i. e.*, three or four hours after eating. When it fails in a case of renal dropsy, a combination of diuretin and digitalis should be tried. I have used diuretin many times in renal dropsy with scanty urine, and I have seen the urine increase from 20 ounces in twenty-four hours up to 146 ounces in the subsequent twenty-four hours. I have never noticed any change in the circulation from its use, and although I employed it for a long time in two cases of renal dropsy, yet it did not seem to increase the arterial pressure at any time. Diuretin has been used with good results in the renal dropsies of children, and R. Demme says that in the dropsy of scarlatinal nephritis, following the first stage of the disease, diuretin is more efficacious than any other diuretic. The dose for children from two to five years old is from three to fifteen grains daily; from six to ten years old, fifteen to forty-five grains daily. In patients whose renal epithelium has undergone too extensive degeneration, the drug may fail.

Spiritus aetheris nitrosi has a reputation as a diuretic in renal dropsy, but it is ill-founded, for it is not sufficiently powerful, even in large doses, to make it worthy of reliance.

Calomel long ago was observed to have a diuretic action, but this seems to have been forgotten during the past twenty years. Its consideration as a diuretic is most interesting, but a long line of clinical observations show that in renal dropsy is has but little power. In cardiac dropsy calomel produces marked diuresis and helps greatly, but in renal dropsy it acts very feebly or not at all.

There have been several new remedies proposed lately for renal dropsy, of which fuchsin and apocynum cannabinum are the most promising, but I have not had any experience with either, and cannot report on their value. There are a great many remedies which stimulate the kidneys and have in a limited way a diuretic action, but most of them are too irritant to be used in dis-

eased kidneys and are too feeble in action to be of any value. We can dismiss most of them by putting them in this list: Pipsissewa, copiaba, cubeba, buchu, uva ursi, pareira, taraxacum and cantharis, juniperus and terebinthina.

MEDICAL PROGRESS

Lung Reflex.—The rather strange and interesting phenomenon, known as the lung reflex, or acute dilatation of the pulmonary alveoli in response to external stimuli, is described and exemplified by A. Abrams (*N. Y. Med. Jour.*, Jan., 13, 1900). Moccucci was the first to suggest this condition when he found that the splenic dulness was diminished by the application of the ether spray. It was afterward found that cardiac dulness could be similarly diminished and in both cases the condition was found to be due to the dilatation of the underlying lung. This was proven by the use of the fluoroscope and by the aid of the conventional physical signs. Mechanical, thermal, chemical or electrical stimuli act similarly and affect only the lung tissue immediately beneath. The practical lessons to be derived are the methods of treatment which may be used in cases of atelectasis and the aid which may be offered in determining whether a local dulness is due to consolidation or to the collapse of the alveoli. In cases of bronchopneumonia of children it is claimed that dulness is often due to areas of atelectasis and these may be distinguished from true consolidation by the application of external stimuli, such as a vigorous rubbing with the hand, but if any lung reflex is obtained it persists for a few moments only and the change in physical signs will be of short duration. Experiments with several kinds of stimuli showed that hot poultices gave unequivocal demonstration of the fact that they were best adapted to counteracting lung collapse and hence especially indicated in bronchopneumonia.

Diplococci a Cause of Erysipelas.—The streptococcus described by Fehleisen has been considered to be the cause of erysipelas. In eight cases of erysipelas G. E. Pfahler (*Phila. Med. Jour.*, Jan. 13, 1900) has found a diplococcus which he thinks may be the cause of the disease. Cover-glass preparations were made with the pus from the pustules of four cases and from the blood of the affected part in all eight cases, and all showed the same diplococci in great numbers. Inoculations were made from each case upon glycerine-agar, blood-serum, and bouillon. In all the tubes pure cultures of this diplococcus only were found. In one case, in which there was a large collection of pus under the scalp, cover-glass preparations showed both streptococci and diplococci. The presence of streptococci in this case, the writer thinks, was due to a secondary infection. The diplococcus, usually encapsulated, is found both inside and outside the leucocytes. It stains easily with aniline gentian-violet, and carbol-fuchsin, but not so well with Löfler's alkaline solution of methylene-blue, with a saturated aqueous solution of methylene-blue, or with Gabbet's solution of methyl-blue.

Growth of Hair.—The popular belief that clipping the hair makes it grow faster, is, according to J. Pohl, not founded on fact. This observer has made accurate measurements of the rate of growth of many hairs under a variety of conditions, found that, if a portion of the head is shaved, the hair will grow for a month more slowly than the hairs of the unshaved portion. After the first month their rate of growth is about the same. He also found that the shaved hairs grew unevenly, and further study showed him that the hairs on the head and elsewhere are arranged in groups of two, three or four, the members of a group being closely related anatomically. One of them outgrows the other for a time, and then its pace slackens while a younger one presses into first place, to be followed by a third, etc. In other words, each hair has a life history and its rate of growth varies at different times. It is most rapid during the middle period of its life. When old, a hair falls out and a young one grows up in its place. As the hairs in a hair-group grow old and fall out successively, baldness is avoided. The average maximum length of the hair of the head is given as from two to three and one-half feet and the average life from two to six years. The growth per month varies from one-half of an inch to an inch or more. (*Dermatologisches Centralblatt*, Dec., 1899).

Genito-Urinary Tuberculosis.—W. Cheyne discusses tuberculosis of the genito-urinary tract (*Lancet*, Dec. 30, 1899). Epididymectomy is an operation worthy of more consideration than it receives. It is contraindicated when the whole of the body of the testicle is diseased; when there is a deposit in the center of the testicle; when there are advanced lesions of the seminal vesicles and prostate, especially with suppuration; when the urinary system is invaded, or when the patient has phthisis in an advanced form. It has a distinct advantage over castration which has a bad mental effect upon many patients, especially upon men of middle age. One can never be sure of getting beyond the disease. In fact there is a strong probability that the other testicle will have to be removed at a later date. Epididymectomy has no such unpleasant mental effect, even if performed on both sides. The technic of the operation is described by Cheyne as follows: The operator stands on the affected side and, turning the testicle inward, makes an incision from the external abdominal ring to the lower end of the testicle. The incision should avoid a sinus. The cord and epididymis are then exposed and the latter, beginning with the globus minor, is separated from the testicle. On the inner side the dissection should be blunt. On the others the tunica albuginea may be incised. If there are diseased spots in the testicle they may be removed. The vas is

followed up through the external ring and then pulled upon and divided as high up as possible. Bleeding should be carefully stopped, and if oozing persists a drain should be left in the scrotum for a day.

The chief end of operation in tuberculosis of the prostate is to drain an abscess, either before or after it has broken into the urethra or rectum. A transverse perineal incision, convex anteriorly, is the best. The urethra and rectum are separated and the levator ani muscle divided. The abscess is then reached and thoroughly emptied, and the wound stuffed with gauze. A catheter should be left in the bladder for ten days. If the abscess has ruptured into the rectum the perineal operation is likely to result in a rectal fistula. It is better, therefore, to dilate the anus and enlarge the opening in the wall of the rectum in order to evacute the pus and clear out the tubercular material by this route.

Ganglia in Tendons.—It has heretofore been considered that a ganglion is an outgrowth from either a joint-capsule or from a tendon-sheath. C. Hofmann (*Central. für Chir.*, Dec. 16, 1899) in the extirpation of a tumor found a ganglion which began in the tendon of the peroneus tertius muscle and had grown to the size of a plum. It contained the fluid ordinarily found in ganglia. It is not difficult to explain this site of the ganglion if one accepts the theory of Ledderhose and others that a ganglion is a true new growth whose slimy contents result from the degeneration of its tissue. However, investigations have not been pushed sufficiently far to enable one to say with certainty that this theory is correct. Possibly in the case referred to traumatism may have had something to do with the origin of the ganglion. In support of the traumatic theory may be mentioned a case reported by Thorn (*Arb. aus der Chir. Klinik der K. Universität, Berlin*, Pt. 14, p. 46), in which a flexor tendon of the forearm of a man aged twenty years was partially ruptured during gymnastic exercises. The tendon underwent reparative changes similar to those which occur after suture of a divided tendon. The processes of repair were also accompanied by degenerative processes and the formation of a cyst whose contents resembled those of an ordinary ganglion.

Wounds of Heart.—Although wounds of the human heart have rarely been sutured, a few successful attempts of this sort have been recorded and interest in the subject is rapidly growing. C. A. Elsberg, who performed a series of experiments upon forty rabbits and dogs in order to determine the outcome of sutured wounds and unsutured wounds of the heart, reports his results in an interesting paper published in the *Beiträge zur Klinschen Chirurgie* (vol. 25, pp. 426-456), and also in the *Journal of Experimental Medicine* (Sept.-Nov., 1899). He found that minute wounds such as those made by the puncture of a needle to not allow the escape of blood from the ventricle while a similar wound in the auricle bleeds freely for a time, but bleeding soon ceases spontaneously. Even if a needle is passed entirely through the heart so as to penetrate both the right and left cavities, bleeding is never severe. The same is true of wounds made with a small scalpel. A wound made during systole bleeds more freely than one made with the same instrument during diastole, for the obvious reason that during the relaxation of the heart from systole to diastole the wound increases in size. Perpendicular wounds bleed more freely than those made diagonally through the heart wall. Wounds of the right heart bleed more freely than those of the left, on account of the more rapid coagulation of the blood in the left heart. Hemorrhage is almost entirely systolic. A wound from two to three millimeters in length in the right ventricle of a rabbit proves fatal unless it is sutured. A much smaller wound in the right auricle will produce fatal hemorrhage. Since a wound which does not penetrate bleeds less than one which does, sutures should not be passed into the cavity of the heart. The visceral pericardium is the toughest of the heart walls and is best adapted to suture; it also bleeds very little. In the larger animals the easiest plan is to confine the suture to the pericardial layer. The only exception to this method of suture is a condition in which the wound is so large that its edges cannot be properly approximated by a suture which does not extend below the pericardium. The heart-beat is only slightly affected by the insertion and tying of sutures, either continuous or interrupted. In certain cases in which the wound is near the apex it is possible to pass a ligature around the heart so that the suture can be carried out without troublesome bleeding, as in a regular Esmarch operation. After the suture is complete the ligature may be removed and the whole heart will then resume its beating as if nothing had happened. The experimenter even found it possible to apply a ligature and to amputate nearly the whole lower half of the ventricle, closing the wound by Lembert sutures. Animals so operated upon recovered. Histological investigation of the repair of wounds showed that in every instance there was a degeneration of the muscle fiber along the stitches, which was replaced by connective tissue. The experiments on animals, together with the limited clinical experience upon man heretofore recorded, indicate that operations on the human heart are not difficult to carry out. On account of the degeneration caused by the stitches, no more than are absolutely necessary should be inserted. Experience and experiments both prove that wounds of considerable size will heal without suture. As far as possible all sutures should be tied in diastole.

Rupture of Puerperal Uterus.—It is said that rupture of the uterus occurs about once in three thousand deliveries. It may occur before or during labor. The causes are well known. J. F. W. Ross (*Am. Jour. of Obstet.*, Dec., 1899)

says that version after the liquo amnii has escaped is the cause in fifty per cent. of the cases. It is not decided whether rupture occurs more frequently in primiparæ or multiparæ. The uterus seems more apt to tear after it is tired out by prolonged contraction. The cervix is the part most frequently ruptured. Ross divides cases of rupture of the uterus into four groups: (1) Those that are beyond hope from the beginning; (2) those which have passed beyond the operable stage and are ill with septicemia and peritonitis; (3) those in whom the rupture is not immediately fatal and who are in good condition for operation; and (4) those in which the rupture is never recognized, but in which a septic condition prevails without known cause. The writer reports two cases in which he was consultant. The first patient was four months pregnant, had hemorrhage, and was evidently threatened with a miscarriage. The physician in charge emptied the uterus. The patient complained of severe abdominal pain and vomited, the pulse became rapid, and the temperature rose. On examination two fingers passed through a rent on the left side of the uterus into the abdominal cavity. A foul-smelling, bloody discharge indicated washing out and drainage from below. This was done for several weeks and the patient slowly recovered. The writer has previously reported a similar case, in which the rupture was caused by the hand of a physician. The second patient had been in labor five hours when the physician arrived. She was a multipara. Fetal movements had been absent for a week. The patient was delivered by forceps of a dead child, because the uterine contractions had ceased and severe abdominal pains suddenly appeared. The pulse increased and temperature rose. On examination the fingers passed through a tear in the cervix and the vaginal vault into the abdominal cavity. Douching with hot water and drainage were employed, and after weeks, during which the patient had all the symptoms of a severe septicemia, she gradually improved and recovered. This case was complicated by a double phlebitis. No treatment will avail in the first class of cases. In the second class, cases like the two reported above, washing out and drainage from below are indicated. In the third class, when the patient is not moribund and the condition is recognized, a thorough inspection and treatment through an abdominal incision is demanded. Ross does not think it necessary to suture the rent in the uterus. In the fourth class, in which there is a septic condition without known cause, thorough exploration of the uterus with the finger is advocated.

Dysentery at Fiji.—The interest in tropical diseases is widening with this country's territorial expansion. C. W. Hirsch (*Edinburgh Med. Journ.*, Jan., 1900) contributes some brief remarks on dysentery as it occurs in Fiji. It is there endemic, being most prevalent in May, June and July, or the season of dry weather and scanty water-supply. While under some circumstances the mortality is high, 40 per cent., the average death-rate, however, is 7 per cent. The symptoms are frequently preceded by constipation and tormina ventris accompanied by tenesmus is characteristic. The greater number of cases recover in from seven to fifteen days. The treatment that seemed to answer best was perfect rest in bed, milk diet, if the stomach was able to retain it; otherwise raw meat-juice, barley, rice-water, sago, arrowroot or some of the prepared foods. If there is much pain, hot turpentine stupes are of service. The medicinal treatment is best begun with castor oil, ℥i., tr. opii., m. 10-15. Ipecac, preferably in keratin capsules, should be administered three times a day in doses of from 15-20 grains.

Wire for Aneurisms.—J. C. Reeve (*Annals of Surgery*, Dec., 1899), cites an interesting case of aneurism of the abdominal aorta treated by him with wire and galvanism. He once used silver-plated, soft copper wire, .016 inch in diameter, introducing seven feet of it through a small needle before obstruction occurred. The positive galvanic pole was then attached and the current gradually run up to 80 milliamperes. This strength of current was continued fifty minutes, when syncope threatened and the treatment was stopped. The tumor had become firm and pulsation had ceased. The wire was left *in situ*. The patient died in twenty-four hours. At the autopsy one end of the wire was found to have traversed the aorta up to the valves, where it had caused an ecchymotic spot. This fact led to the inquiry as to the proper wire for such cases. A bladder was hardened to represent an aneurismal sac, with an aperture corresponding to the arterial communication, and many varieties and sizes of wire were introduced. The soft, untempered wires could not be introduced in sufficient amount because of kinking at the needle. In order to keep the tempered wires from escaping into the vessel from the sac, it was necessary to have them coiled before introduction into the sac. They then tended to coil again within it and not to escape. The requirements were best fulfilled by either a silver or gold wire, .0085 inches in diameter, of sufficient temper to retain its coil. Such wire will not break during its extraction.

Phenylhydrazin Test for Sugar.—This test has been heralded far and wide as the only certain one for the detection of glucose in diabetic urine. Yet, in recent years a number of investigators, following Von Jaksch's experiments, find that he was not warranted in assuming so broad a statement as to its efficacy for the detection of glucose. They aver that they could obtain the neeedle-like crystals of the phenylglucosazon in urine that was practically free from sugar and that, therefore, this test is not applicable in urinalysis. This uncertainty stimulated further researches on the part of Paul Meyer, assistant to

Professor von Leyden in Berlin (*Berlin klin. Wochen.*, Jan. 1, 1900) who directed his experiments chiefly to determining the part played by glycosuric acid in the formation of the characteristic crystals. He states that in no case in which he used normal urine could he obtain the crystals or anything else, in fact, that might be mistaken for them. However, he also states that as glycosuric acid never occurs free in urine, and as its combinations and compounds as such never enter into combination with phenylhydrazin, it might be assumed that no phenylhydrazin compound found in the urine could be formed partly by glycosuric acid. And yet it can be readily imagined that the glycosurates might be decomposed in the process of heating and then unite with the phenylhydrazin to give the needle-like crystals. The author consequently administered drugs that would form weak compounds with glycosuric acid, which compounds would readily decompose on heating, giving off free glycosuric acid. Such drugs he found to be naphthol, thymol and menthol. In the resulting urine he found that the thymol and naphtholglycosuric acids never entered into combination with phenylhydrazin, while with mentholglycosuric acid the test indicated quite a different result. After five grams of menthol had been taken internally, the urine was examined and found: (1) to reduce Fehling solution, (2) to polarize to the left, and (3) to give beautiful phenylglucosazon crystals with phenylhydrazin; although the day before taking the drug the urine was perfectly negative in all these respects. So it is clearly seen that grave errors in diagnosis might still be made if this much vaunted test were depended on entirely. Yet the author says that if there be no positive fermentation test then sugar is not present and with this as the keynote the phenylhydrazin test should be tried. In a very rare case he has seen the administration of chloral hydrate (forty-five grains) followed by a positive reaction with phenylhydrazin when no sugar was present. In spite of all these facts, Meyer declares that the realm of usefulness of the phenylhydrazin test is not appreciably narrowed if one will only carefully exclude the disturbing factors, such as the previous ingestion of menthol or chloral. The statement nevertheless that "every urine which reacts with phenylhydrazin to produce phenylglucosazon contains sugar," must certainly be modified so as to be somewhat less general in character.

Postural Treatment in Tabes.—A. H. Lindström (*Boston Med. and Surg. Jour.*, Jan. 11, 1900) reports a case of tabes in which the pains were successfully treated by mechanical means alone. The patient, a man forty years old, had had pains for ten years, but the other tabetic symptoms did not manifest themselves until during the last year. He had been unwilling to take drugs for the pain, lest he should contract a drug habit. But the pains had been so severe that he finally resorted to whiskey freely during an attack. There was no doubt of the diagnosis. His family and personal history were good—no syphilis or alcoholism. He had, however, fallen about thirteen years ago and injured his back. At the time of beginning treatment the patient had been unable to sleep for ten days because of the severity of the pains. Still he would take no drugs although frantic with pain. Lindström decided to try stretching of the sciatic by posture, namely, by flexion of the thigh and extension of the leg and foot. Each sciatic nerve was kept in a state of tension for two minutes at the first treatment. There was numbness of the feet and slight distress in the poplitcal space following the treatment, but freedom from pain for several hours. On attempting to walk, the ataxia had apparently increased, but this was probably due to the numbness of the feet, since the gait improved as the numbness wore off. The patient was able to get several hours' sound sleep. The following day each sciatic was kept in tension for three minutes. The numbness of the feet and the apparent increase of ataxia immediately followed the treatment as before, but were perhaps more marked. The absence of pain was more complete. The patient slept well all night long. A third treatment was given, two minutes to each sciatic. No pains having appeared, the next stretching was done two days later, and a fifth, and last, treatment forty-eight hours after that. During all this time the patient had been practically free from pain. Since these treatments he has had only a few light attacks of pain, usually caused by injudicious physical exercise. The general treatment of the case was tonic, eliminative, and hygienic, with the addition of systematic co-ordination exercise. In the early stages of tabes the hip-joint is extremely flexible. Lindström was able, after flexing the thigh upon the abdomen, to bring the patient's leg and foot on the level with his face. Care must be taken, in doing this, not to use undue force, or any sudden pressure. Subluxation at the hip-joint must also be guarded against.

Gall-Stone Crepitus.—All clinicians of wide experience have met cases in which the features of gall-stones in the common duct or gall-bladder as the cause of a chronic jaundice or more indefinite general symptoms have been too incomplete for an assured diagnosis. J. M. Anders (*Internat. Med. Mag.*, Dec. 1899) has reported a number of cases in which this physical sign was made out and proved to be of great diagnostic value. The crepitus may be obtained by palpating with the finger-tips dipped gently but deeply in the abdominal wall just below the fundus of the gall-bladder and then drawn upward over the organ as though making an attempt to roll the fundus upward and forward. Deep inspiration is helpful and the lactile sense of the palpating fingers may be increased by pressing on their dorsal surfaces with the disengaged hand, thus relaxing the muscles of the examining hand. Auscultation is sometimes successful when palpation fails and a

combination of the two has led to the detection of a friction-sound when other methods had been tried in vain. In attempting the latter mode of examination, the stethoscope should be placed just below the costal arch, in order to allow space for the palpating right hand over the fundus of the gall-bladder.

Gall-Stones.—H. McGuire (*Georgia Jour. of Med. and Surg.* Dec., 1899) says that gall-stones are most common in middle-aged women, especially such as lace, overeat and lead sedentary lives. The characteristic symptoms, pain, swelling of gall-bladder and jaundice, are rarely all present in one case. The pain is paroxysmal, colicky, radiating from the gall-bladder, and is due to spasmodic contraction of the gall-bladder in the attempt to overcome the obstruction in the ducts. This obstruction is due to inflammation of the duct and not to the presence of a stone in the duct, for colic is rarely followed by the passage of a stone, and discharge of a stone is frequently not preceded by colic. Tenderness is present only with local peritonitis. The distention of the gall-bladder is more dependent on the elasticity of the walls of that viscus than upon the degree and site of the obstruction. The walls may be thick and contracted, enclosing no fluid; or they may be thin and distended with mucus mixed with bile. In stone of the cystic duct the viscus is sometimes empty, but more often it is filled with pure mucus. In stone of the common duct it is filled with bile. In either case, after infection, its contents become purulent. Jaundice is the symptom most misunderstood. At least half of the patients with gall-stones never have jaundice, and half of the cases of persistent jaundice are not due to gall-stones. If the stone is in the gall-bladder there is usually no jaundice or but a slight and fleeting discoloration. If the stone is in the cystic duct it causes jaundice by pressure on the common duct. If the stone is in the common duct jaundice varies with the completeness of obstruction. The Roentgen rays give no diagnostic assistance since the stones are chiefly cholesterin (*i. e.*, fat). The question of operation depends on the frequency and intensity of attacks and their effect on the patient's mental and physical condition. When there is constant pain, perceptible distension, persistent jaundice, or threatening suppuration, immediate operation is desirable. The danger of the operation is about the same as that of appendectomy. Of the various operations, drainage of the gall-bladder through the abdominal wound has the lowest mortality, and is the one to be chosen in the majority of cases. The "ideal operation" involving closure of the gall-bladder and the abdominal wound is undesirable except in cases in which the walls of the viscus are healthy and no adhesions exist. After opening either of the ducts, tension on the closing sutures should be avoided and physiological rest for repair given by draining the gall-bladder after suturing it in the abdominal wound.

Gonorrhea in Women.—The chief seat of gonorrhea in women is undoubtedly the urethra. So long as the infection exists in this locality, albeit that all the surrounding parts have responded to treatment, the danger still lurks for the unwary. G. E. Shoemaker (*Thera. Gaz.*, Dec. 1899) considers this specific disease in women with special reference to the urethal infection. The first point in the therapy upon which he insists strongly is rest in bed. Of course, the general instructions regarding cleanliness of the vulva, hands, and the immediate destruction of soiled dressings are insisted upon. There should be frequent mopping of the parts with weak carbolic acid, boric acid, creoline or permanganate solution. Three or four times daily the same solution may be used in a copious vaginal douche. The labia are to be separated by a thin layer of lint or cotton saturated with a solution of lead and opium. Plenty of water should be drunk and salol or boric acid administered for the purposes of diluting the urine and rendering it aseptic, at the same time allaying bladder and urethral irritation. As soon as the tenderness has become lessened sufficiently to allow the use of instrumentation local treatment must be adopted. Especially important is this in the urethra. Injections of boric acid may or may not be used and should be followed by suppositories of ichthyol or iodoform inserted into the canal. A mixture of ichthyol and glycerine, 1-5 or 1-10, applied with applicator, is to be recommended. Skene's treatment of the urethritis is advised, *viz.*, two or three times daily this canal is washed out with a fluted reflex catheter, followed by the introduction of suppository of iodoform or of bismuth subnitrate in cocoa butter. When the disease is chronic, direct applications of nitrate of silver, 1 to 5 per cent., may be applied to the reddened and inflamed patches which are chiefly found at either extremity of the urethra. If injections are practised, care should be exercised not to use too much fluid at one time. The two tubular glands along the floor of the urethra sometimes do not respond favorably to nitrate of silver. In that case they must be slit up. Treatment must be carried on until the gonococcus can no longer be found in the discharges. If recurrent abscesses form in the vulvovaginal glands the best treatment is to dissect them out. After the cervix and urethra have been treated and ichthyol and glycerine applied, a light vaginal pack of borated or iodoform gauze should be inserted.

Fractures of the Leg.—W. L. Estes (*Internat. Jour. Surg.*, Jan., 1900) advises the use of plaster dressing for fractures of the tibia if proper apposition is easily maintained. In oblique fractures with constant tendency to overriding he advocates local fixation if the conditions favor aseptic work. His method consists in incision down to the site of fracture, removal of shreds of tissue, clots and detritus, careful apposition of the fragments, and their fixation by a nickel-plated steel plate, extending across the line of fracture and held in position by ivory pegs. The wound

is closed and covered with sterile dressings and an outside plaster bandage. After three weeks the dressings are removed and if union is fairly firm the fixation plate is taken out, the wound closed and another plaster dressing applied. This is to be left on about three weeks more. When a patient wearing a plaster-cast is allowed to use crutches, it is very important that he should wear a raised shoe on the sound foot. In most cases splints are discarded in five weeks, and massage, daily passive joint movements and gradual active movements are instituted. Ambulant treatment is applicable only to transverse fractures or oblique fractures, with no tendency to displacement of the fragments.

Local Hot-Air Treatment.—The fact that the body can stand high degrees of local temperature much better in perfectly dry air induced E. Lindemann (*Klin. ther. Woch.*, Dec. 24, 1899) to construct an apparatus heated with electricity which, he claims, lacks all the disadvantages of the older contrivances warmed by gas or alcohol. General hot baths cause a short contraction followed by a prolonged dilatation of the vessels of the skin; the heart's energy is reduced; there is diminished diuresis, increased sweat and metabolism. Local baths, while they affect the skin similarly, do not disturb circulation so generally; thus there is little danger in using them in heart disease. Their chief action depends on the heat, a high degree of which will cause local perspiration with increased absorption of transudates and exudates in the joint treated, resulting in less pain and greater mobility. These baths are especially valuable in arthritis deformans, gout, rheumatism, old dislocations and gonorrheal joints.

Cerebral Rheumatism.—There are cases of acute articular rheumatism which are complicated by a set of cerebral symptoms so severe and marked as to give their characteristic stamp to the course of the disease. The term cerebral rheumatism is applied to such cases. High temperature in almost any acute disease may give rise to marked cerebral symptoms—headache, restlessness, sleeplessness, stupor, delirium, or convulsions. Some cases of acute articular rheumatism are accompanied by very high temperature and marked cerebral disturbance, such as we should expect from our knowledge of the effect of high fever upon the brain. Therefore, the term cerebral rheumatism usually brings to the mind the thought of hyperpyrexia and its attendant cerebral disturbance. P. Morgan (*Phila. Med. Jour.*, Jan. 13, 1900) cites a number of writers who seem to think that cerebral rheumatism is due to the effects of a high fever on the brain, and also two who think there must be some other cause for the cerebral disturbance. He believes that cerebral rheumatism and hyperpyrexia are two distinct and separate complications of acute articular rheumatism, that the symptoms of cerebral rheumatism are not dependent upon high fever, although it may be present, that hyperpyrexia may present symptoms very similar to those of cerebral rheumatism, and that true cerebral rheumatism is due to a toxic agent in the blood, which acts on the brain and its membranes, producing the characteristic symptoms. Predisposition plays an important part in the production of cerebral rheumatism. The writer cites a case in support of the opinion that true cerebral rheumatism is not primarily due to the effects of hyperpyrexia and that it may occur without high fever, in which the temperature only once went above 102° F. after the cerebral complications appeared. As to the nature of the toxic agent causing cerebral rheumatism, investigations and conclusions of numerous writers here cited tend to show that the disease is an infectious process caused by the presence and growth in the body of the ordinary pus cocci. If this theory be proved correct, all the symptoms of the disease will be easily explained as due to the toxic effects of products elaborated by the pathogenic bacteria. According to Pepper, cerebral rheumatism occurs in about three to four per cent. of all cases of rheumatic fever. In the majority of cases of cerebral rheumatism no pathologic changes are found in the brain or membranes after death. Occasionally there are changes found. When this is the case there is always a strong suspicion that a meningitis complicated the articular rheumatism, and not a true cerebral rheumatism. The symptoms of the disease usually begin with mild nocturnal delirium, headache, disturbance of vision, and subsultus tendinum. Sometimes there is profuse perspiration and vertigo. As the disease progresses, the most prominent symptoms are cerebral excitement, great restlessness deepening at times into convulsions, and coma. Coma is rare, except in the last stage of fatal cases. The delirium is generally a quiet, talkative kind, with hallucinations, but sometimes is noisy and violent. The hallucinations are usually of space and time and general surroundings. Distrust and ideas of persecution may be present. There may be disturbances of the special senses with the characteristic symptoms. The motor portion of the brain is affected and there is restlessness, tremors, choreic jactitation, and even convulsions. The diagnosis is usually easy, as the above symptoms are characteristic. Care must be taken not to mistake the symptoms due to large doses of the salicylates for those of cerebral rheumatism, as they very closely resemble each other. Two cases are reported showing the symptom-picture due to large doses of salicylates. The prognosis in cerebral rheumatism is bad. In 107 cases reported there were 57 deaths and 50 recoveries. The treatment is wholly symptomatic. The salicylates appear to have no effect upon the condition.

Tetanus in Cuba.—General Wilson, the military governor of Matanzas and Santa Clara, Cuba, says that tetanus is universal in Cuba. A wound in the foot of human beings or of an animal is almost sure to result in lock-jaw.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

THE PRETUBERCULAR STAGE OF CONSUMPTION.

IT has always been considered the great desideratum of pulmonary diagnosis to be able to recognize the invasion of tuberculosis before actual caseation and the formation of tubercular nodules have taken place. From the modern standpoint of the curability of consumption in its incipient stages, it is more imperative than ever that this preliminary pathologic condition should be diagnosticated. The possibility of doing so seems now quite within the physician's grasp. Certain signs in the nervous system occur early in the affection, before any other symptoms are noticeable, and give at least a very suggestive hint of the presence of the disease.

We called attention some time ago to the fact that the varying pathologic conditions due to interference with the vasomotor system at the ends of the extremities had been pointed out as occurring in certain cases as a preliminary to the development of tuberculosis. This whole class of diseases, from the mildest erythromelagia to mutilating Raynaud's disease, presents a picture of disturbance with peripheral circulation which, when it affects the periphery of the pulmonary circulation, provides ideal conditions for the lodgment and culture of tubercle bacilli.

The toxins of the tubercle bacillus possess the special power of acting upon the capillary circulation and of producing disturbance of such functions as are usually considered under the control of the sympathetic system. A slight hectic flush not due to fever, long before any physical signs of the disease is demonstrable, is in so-called consumptive families the prophetic mark of the next victim to be attacked. A pronounced tendency to perspire easily is another characteristic of the pretubercular stage of the disease. Dr. Harrington of Lowell, Mass. (*Boston Med. and Surg. Jour.*, Dec. 7, 1899) calls attention to an early sign of tuberculosis, which consists of widely dilated pupils. This is, of course, another region which is innervated by the sympathetic, and although the symptom is one that occurs in many conditions, notably in neurasthenia, it has its value as a confirmatory sign of beginning invasion of the tubercle. It has long been noted that patients with incipient tuberculosis often have capricious appetites and are liable to gastric symptoms, alternating with diarrhea. These symptoms have been attributed by good authorities to irritation of the vagi. In these conditions, too, the sympathetic plays an important rôle. The "intestinal blush" which is supposed to account for the looseness of the bowels incident to intense excitement and emotion will be remembered and will serve to show the source of these disorders. In a word, very early in the development of the tubercle bacillus in the human body, certainly before any breaking down of tissue has begun, an absorption of toxic materials in very slight amounts occurs. This affects only the most delicate nervous mechanisms in the body, *viz.*, those controlled mainly by the sympathetic system. The series of symptoms thus produced cannot fail to be of service to the accurate diagnostician in detecting very early stages of tuberculosis. Early detection with open-air treatment, regulation of life, and liberal, carefully selected diet, means in our day absolute cure, made permanent under favorable conditions.

FADS IN THE STUDY OF EPILEPSY.

THE very obscurity in which the subject of epilepsy and kindred functional neuroses lies renders them objects of vague wonder and speculation. The true etiologic pathology of such dis-

eases is practically hidden and unknown, and with our present means of investigation it is liable to remain so for some time.

The currently accepted etiology of epilepsy is that a more or less pronounced congenital predisposition exists in 85 per cent. of all cases of epilepsy (Gowers). Upon this predisposition a mild or severe excitant is superimposed at the inauguration of the disease. The relative equation between the predisposition and the excitant is left, however, to the individual clinician's judgment.

One of the greatest problems in epilepsy today is the solution of the hereditary instability of the cerebral cortex. As has been frequently pointed out, such studies must largely rest for ultimate solution upon pathologic chemistry, experimental physiology, and physiologic psychology; the latter method is still practically untried. If psychopathic hospitals are to be established, clinics embracing these lines of work should be given their respective places in the scientific investigation of mental and nervous diseases.

In connection with the etiologic pathology of epilepsy, it is interesting to note the recent aberrant forms or fads in its study. For some time the fashion has been to study epilepsy in its extraneural origin, a line of investigation mined to its utmost in years past. As a result of the revival of the study, we have the autotoxists and reflex neurologists; those tampering with the unbalanced eye muscles, the elusive ovary, and the secretive ductless glands. Dr. Ohlmacher is among those most prominently engaged in the last kind of investigation. In Volume I., combining Numbers 2 and 3 of the 1899 issue of the "Bulletin of the Ohio State Hospital for Epileptics," Dr. Ohlmacher has revealed to us that a lymphatic hyperplasia is the real basis of idiopathic epilepsy. In fact he contends that idiopathic epilepsy should be called *lymphatic epilepsy*, and status epilepticus, *status thymicus*. The author naïvely suggests when the lymphatic structure is found atrophic in epileptics that hyperplasia was *once* prominent. In regard to the completeness of evisceration of Dr. Ohlmacher's post-mortems, the neuropathologist's envy is largely removed by the bitter experience that the collected specimens of to-day, in the light of an ever-changing preservative, may be all declared useless to-morrow.

The very meager clinical data which Dr. Ohlmacher's studies show is nowhere more appallingly in evidence than in the twenty lines of history which are devoted to the complete presentations of the "status" case; the fever curve is not even demonstrated, which is the absolute essential of status epilepticus. On the whole, the overtrained thymic acuteness of Dr. Ohlmacher's investigations will unfavorably prejudice many seekers after truth. In striking contrast to this author's pathologic explanations of epilepsy on the incomplete study of a few cases, stands the monumental work on this same subject by the illustrious Bourneville, who, after the investigation of hundreds of autopsies in the disease, covering a period of continuous research work of more than twenty years, is still utterly unable to formulate even a plausible theory of epilepsy.

Without attempting to be overcritical of scientific work, we cannot too heartily condemn pseudo-science, or the fad study of any disease. This is signally true in the study of epilepsy, where already such work has been done to great excess.

THE RULES OF THE GAME OF BULLETS.

The maxim that "all is fair in love and war" is no longer the code of lovers or of soldiers. The rape of the Sabines, or Lochinvar's daring escapade is praised only in the light of the then existing status of woman. As in love, so in war, sentiments have changed. The torture of prisoners, the use of poisoned missiles, the betrayal of the enemy under a white flag—these things have all been crossed from the code of the fighting man. There has been a growing sense of the sacredness of human life, in both the military and civil forces of the world, and a constant struggle has been going on between the desire to save life and the desire to kill. This explains certain grimly humorous inconsistencies in the game of bullets.

In order to carry long distances, bullets are made long and slim, with a conical point, steel or a composition equally hard being the material employed. As a bullet needs weight, it is usually made filled with lead. Such is the well-known Mauser bullet. Such a missile destroys a track through the body not much wider than its own diameter. Its capacity for destruction in this form is scarcely worth mentioning. File the steel from its tip, so as barely to expose the lead core, and when the bullet strikes it spreads and plows an ever-widening path through the body. Its track of destruction is then a slender cone, and the wound of exit is four or five times as wide as that of entrance. This bullet is called Mark II.

If the lead core projects a fraction of an inch from the steel mantle, it is flattened as soon as it strikes the body. Driven through bones and soft tissues by the terrific impulse behind it, this flattened ball cuts a swath which would do credit to a good-sized fragment of a shell. This is the famous Dum-Dum. But the crowning glory of the bullet-maker is called Mark IV. Its lead core is exposed at the tip and besides a hole is bored from the conical tip right down to the center of the bullet. Thus aided in its expansion, Mark IV. can destroy a track through the body which measures ten inches across at the point of exit. If fired into a skull filled with plaster-of-Paris about to set, the whole skull will be scattered in pieces over the floor, as if it had exploded. Now, as to the English ethics of these bullets: Mark IV. for elephants and tigers, who carry no fire-arms; the Dum-Dum for natives with spears and arrows, and Mark II. for the Boers who, by the way, use Mausers.

England's use of expansile bullets has been severely criticised on the Continent on grounds which appear ludicrous to a man of peace. Why not take a ten-inch cone out of a man's back if you are trying to kill him? The sum of the matter is that humanity and war don't mix and a battle in which the soldiers are no longer able to take delight in the carnage is as poor fun as horse-racing without betting.

ECHOES AND NEWS.

NEW YORK.

Hospital Luxury.—The Kings County Charity Hospital is up to date, and, in some respects, ahead of it. Its new wings are equipped with roof gardens for the use of patients. Other hospitals might make a note of this.

Bequest to Charity.—By the will of Dorman B. Eaton, who died in New York, December 23d, the Society for the Suppression of Vice receives $25,000 and the New York Skin and Cancer Hospital $10,000. In addition to these bequests Columbia and Harvard Universities each receive $100,000.

Cigarette Law.—A bill has been introduced in the Legislature at Albany, providing for the better protection of the public health in the manufacture and sale of cigarettes. No cigarettes shall be sold to persons under eighteen years of age. A penalty of $50 fine or sixty days' imprisonment is provided.

State Sanatoria for Consumptives.—The Charity Organization Society has obtained, through its special committee, the opinions of various representative societies of the State that are interested in this subject. Opinion seems to be divided between the establishment of new sanatoria and of giving State aid to those already established, as the Saranac Sanatorium and the Loomis Sanatorium.

Purity and the Police.—New York would seem to have reason to congratulate herself in the versatility of the members of its police force. One of the latest reported adjuncts to the city's "Finest" is the running of one of the Tenderloin's most notorious resorts by one of its members. When the guardians of public morals "stand in" in this way with the perverters of youth, what can be expected of our future generation of young men?

Contagious Diseases.—The health department submits the following report of contagious diseases for the week ending January 13, 1900: Measles, 757 cases and 25 deaths; diphtheria, 276 cases and 41 deaths; laryngeal diphtheria (croup), 15 cases and 12 deaths; scarlet fever, 226 cases and 6 deaths; smallpox, 1 case; chicken-pox, 37 cases; tuberculosis, 125 cases and 145 deaths; typhoid fever, 47 cases and 15 deaths; cerebro-spinal meningitis, 2 deaths.

A Human Ostrich.—A young man, twenty-two years of age, was taken ill recently, in Brooklyn, with symptoms of gastritis. By means of the X-ray various articles of hardware were located in his stomach. January 14th he submitted to gastrotomy with the result that there were taken from his stomach two keys, six hair-pins, one hundred and twenty-eight common pins, ten 2-½-inch iron nails, two horseshoe nails, three chains, one brass and two nickel, and a finger-ring with a stone setting.

Assistant Surgeon Bill.—The New York County Medical Association, at its meeting on January 15th, indorsed Senator Platt's bill for the purpose of giving the same status to acting assistant surgeons of the United States Army that is given to the acting assistant surgeons of the Navy. Resolutions were adopted requesting the delegates to the American Medical Association and the State Medical Association, when selected, to present the bill to these associations and inform them of the County Medical Association's action.

Oppose the Death Penalty.—The Association to Promote the Abolition of the Death Penalty was formed last week, at a meeting held at the Friends' Seminary, at Sixteenth street and Rutherford place. Gen. Newton M. Curtis presided at the meeting and was selected as president of the association. Ernest H Crosby was chosen vice-president, Franklin T. Carpenter, treasurer, and John W. Hutchinson, secretary. Assemblyman Maher was present and said that he would introduce a bill in the Legislature shortly to do away with the death penalty and that he had strong hopes that it would pass.

Water Shortage.—So serious are the prospects of a water famine in Brooklyn that the depart-

ment authorities have arranged to make use of ponds near Jamaica. These ponds were formerly condemned by the State Board of Health on the ground that they were polluted by numerous nuisances, existing along the streams which supply them, and the water unfit for human use. It is estimated that about 6,000,000 gallons a day will be obtained from the ponds. Before the water is turned into the mains, however, public notice will be served to boil all drinking water. When these arrangements go into effect the Brooklyn health authorities may expect a prompt increase in the mortality rate.

Antitoxin *vs.* Chlorine.—War has again been declared by Mr. Russell, the champion of the use of chlorine gas in the treatment of diphtheria, and the New York Board of Health. Mr. Russell again charges the board with intolerance in not being willing to give the chlorine treatment a fair trial in the public institutions. On the other hand, the members of the Board personally affirm that a fair test of the chlorine treatment has already been made in the Willard Parker Hospital in a series of cases and found ineffectual to such a degree that they do not feel justified in continuing its further use. It would appear that Mr. Russell's statements require investigation rather than those of the Board of Health.

Koplik's Spots.—Aldrich, in an editorial in the December issue of the *Cleveland Medical Gazette*, sorrowfully regrets that he must rob Dr. Koplik of the credit of his discovery. In answer to the statements contained in this editorial, Dr. Koplik writes: "My first article appeared in the *Archives of Pediatrics*, December, 1896, and was entitled 'The Diagnosis of the Invasion of Measles from a Study of the Exanthema as it Appears on the Buccal Mucous Membrane.' I do not think that Dr. Weiss and Dr. Aldrich could have read my first article carefully; otherwise they would have seen that I described the *buccal sign only* as *pathognomonic* of beginning measles. Dr. Flindt (Jurgensen's translation) describes a spotted exanthema upon the soft and hard palate, the arch of the fauces, the mucous membrane of the cheeks and lips, and also the conjunctivæ. He speaks of vesicular formations in the center of the red spots, but he makes no mention of the *buccal* exanthema as the *only* pathognomonic sign of beginning measles."

Inspection Not Permitted.—The Court of Appeals, January 9th, handed down its decision in the case of the State Board of Charities *vs.* the New York Society for the Prevention of Cruelty to Children. By a vote of four to three it decided that the latter society does not come within the jurisdiction of the State Board of Charities. The decision is a far-reaching one, greatly restricting the powers and duties of the State Board. It says: "The scheme of State supervision was not intended to apply to every institution engaged in some good or commendable work for the relief of humanity from some of the various ills with which it is afflicted, but only to those maintained in whole or in part by the State or some of its political divisions, through which charity is dispensed by public authority to those having a claim upon the generosity of the State." This evidently means that no charitable institution or society is subject to the inspection of the State Board of Charities unless it receives public funds. No wrong can be done to any charitable institution that depends upon the beneficence of the public for its existence by an inspection at stated intervals by the State Board of Charities. The law should, therefore, be amended in such a way as to bring all these institutions within its scope. Many charitable institutions in New York that were established and supported originally by private donations have become so wealthy through the rise of real estate that they are able to defy public opinion and proper investigation.

The State Prisons.—The State Prison Commission submitted its report to the Legislature last week. The population of the State prisons, reformatories, penitentiaries, houses of refuge, and jails has decreased during the past year 741, standing now a little above 10,000. The decrease in the penitentiaries considered alone is 2387 since 1895. In the belief that nothing should be done to crush the prisoner's self-respect or unnecessarily humiliate him, the commission suggests that the prison authorities consider whether the lock-step should not be abolished. The commission condemns the present method of grading state prisoners according to the number of convictions, and contends that the prisoner's grade should depend upon his conduct in prison. The present system of employing convicts has made satisfactory progress, and is furnishing a reasonable amount of employment to the convicts. The law relating to the parole of convicts in the State prisons should be amended so that all prisoners, committed to state prisons for all terms (other than for life) shall be subject to the jurisdiction of the Board of Parole; that the term of sentence shall be treated as the maximum for which they may be detained; and that all prisoners, except life prisoners, may be paroled under proper restriction, and under rules and regulations to be made by the Board of Parole, care being taken that when prisoners are paroled they shall be provided with employment, enabling them to earn an honest livelihood.

Exhibition of Plague Bacilli.—At the meeting of the Section on Medicine, January 16th, Dr. William H. Park of the laboratories of the New York Board of Health exhibited, under the microscope, specimens of the plague bacillus. These specimens were cultivated from bubonic pus taken from the captain and the cook of the coffee steamer "W. R. Taylor," recently quarantined upon her arrival from Santos at New York harbor. The specimens taken from the bouillon culture showed the bacilli arranged in chains; those from the agar were in groups and were individually thick and fat. These are the first specimens of plague bac-

illi that have ever been developed from cases of plague in this country. The specimens derived from the captain and the cook were identical with each other, and with some slides that had been obtained from India and from China.

At the same meeting Dr. F. S. Fielder presented a report upon some experiments made by him in the use of caustic potash to denude the skin preparatory to vaccination, instead of the ordinary methods of scarification. Dr. Hutchins of Georgia had announced that the pain of vaccination could be obviated, and the flow of blood prevented by this method. The use of caustic potash was recommended for use in cases of nervous children, as it obviated the use of any instrument and the drawing of blood. Dr. Fielder's experiments justify these claims for the method, but he did not find the method as successful as the ordinary inoculation after scarification with a needle or a lancet. More than thirty per cent. of the cases failed to take, although an equal number of cases vaccinated at the same time, with the same virus, were all successful. The failures were found to be due to a certain parchment-like condition of the skin caused by the potash, through which the virus could not ordinarily penetrate. Dr. Fielder was ready to admit, however, that the advantages of the method rendered it quite worthy of trial in cases of hysterically nervous children.

PHILADELPHIA.

Health Reports.—The number of deaths in the city for the week ending January 13th was 504, a decrease of 9 from last week and a decrease of 38 from the corresponding week of 1899. Contagious diseases: Scarlet fever, 78 new cases, 6 deaths; diphtheria, 137 new cases, 28 deaths; enteric fever, 32 new cases, 1 death.

Hospital Reports.—Officers for the year have been elected by the West Philadelphia Hospital for Women and the Polyclinic Hospital. The report of the Board of the latter shows a remarkable increase in its work during the past five years. In 1899 there were 1007 more free-bed days recorded and 1883 more accident cases treated than during the previous year.

Death-Rate, 1899.—The total number of deaths reported in Philadelphia during 1899 was 23,796, or a ratio of 18.78 per 1000 of estimated population. This is the lowest ratio reported since the year 1888, when the rate was only .06 per cent. lower. Of the whole number of deaths during the last twelve months 4560 were of children under one year of age and 2496 between the ages of one and five years.

Results of Hanging.—The body of the negro hanged last week for the murder of his wife was taken immediately after being cut down to the dissecting-rooms of the Jefferson Medical College. The body was examined by members of the faculty of Jefferson and the University of Pennsylvania, and experiments were made regarding the persistence of muscular contraction, etc. It was also demonstrated that both the carotids were severed by the hanging. The results of the examination will be published.

Closure of Schools.—An epidemic of diphtheria and scarlet fever is prevailing at Scranton. The health officer has been given authority to close schools without asking the advice of the Board of Health. It is believed by the authorities, however, that the negligence of parents plays the greater part in the spread of the disease. For every case traced to a school ten could be found that originated from infected children playing with others in the streets or about their homes. This was allowed by parents after their children had been suspended from school.

Ruling of State Board.—The announcement of the State Board of Medical Examiners that graduates who have had but three years at a medical college are not eligible for examination has provoked a great deal of discussion. This ruling applies to college graduates whose degree has been accepted in lieu of the freshman year at the medical college. Among those taking part in the discussion as to the desirability and legality of this ruling are Dr. W. W. Keen, Dr. Henry Beates, Jr., of the Board, and Dr. H C. Wood. The latter believes that even seven years devoted to the exclusive study of medicine would not be too long a course. He would divide the physician's preparation as follows: Two years in college; four years in a medical school; one and a half years as a hospital resident; one and a half years in post-graduate study in the capitals of Europe.

History Repeats.—There is an old story told of a sufferer from melancholia who called upon a famous London physician in the early part of this century. The man of drugs tried all the resources of the materia medica, but in vain. At last he said: "You should go to see something funny at the theatre. Try Joseph Grimaldi."

"Alas!" replied the patient, "I am Joseph Grimaldi."

Why repeat this story now? Because after numerous avatars it has finally reappeared in the following form: Dr. S. Weir Mitchell, nerve specialist and novelist, while on his recent foreign tour, called upon an eminent German neurologist to consult him about a nervous trouble. He sent up a card inscribed simply, "Mr. Mitchell of Philadelphia."

The German examined him very carefully. Then he said: "My dear sir, do I understand that you come from Philadelphia?"

"Yes."

"Well, you should have consulted Dr. S. Weir Mitchell of that city."

"I am Dr. S. Weir Mitchell," was the answer.

Appendicitis Mortality.—At a meeting of the Philadelphia County Medical Society, January 3d, Dr. W. J. Hearn took exception to the title of a paper recently read in which the "great mortality" of appendicitis was mentioned. He considers the mortality rate to be low when the large

number of cases and the many different operators are taken into account. At the Jefferson Hospital 120 cases have been operated upon with 8 deaths, a mortality of 6⅔ per cent. His own record is 50 cases with 2 deaths, a mortality of 4 per cent. Both these cases died from metastatic abscesses of the liver. In 20 of his cases the pus-cavity was evacuated and drained and the appendix not removed. At the Jefferson, operation is done as soon as the diagnosis of suppurative or ulcerative appendicitis is made; catarrhal cases are often not operated upon for the first attack. If there is no pus tumor Dr. Hearn makes his incision as near the anterior superior spinous process as he can. This is believed to guard against the occurrence of ventral hernia, as there are no loops of small intestine at that place and the colon is, of course, held by the meso-colon. If the appendix is readily reached it is removed; if not, it is left. Secondary operations are more often necessary because of secondary pus-cavities not opened at the time of the first operation than because of appendix stumps allowed to remain. If no limiting exudate has been secreted and the pus has worked into the pelvis or to the left side of the abdomen a counteropening is made in the left side, the abdominal cavity is washed through and through and drainage inserted. Most cases of fecal fistula are in the large intestine and heal spontaneously. An abdomen opened once has a certain tolerance for secondary operations. The cases that die are those in which operation has been delayed or are fulminant in character or have septic peritonitis.

Prevention of Tuberculosis.—A joint meeting of the Philadelphia County Medical Society and the Pennsylvania Society for the Prevention of Tuberculosis was held Wednesday evening, January 10th. The speakers included many of the prominent physicians of this city and also Dr. E. O. Otis of Boston. Dr. Solis-Cohen stated that Philadelphia as the medical center of the United States should not be behind other cities in solving the problem under consideration. The State also should recognize that the work of educating the people regarding tuberculosis is too great for individual effort and State aid should be given. People should be educated in the improvement of vital resistance and in the avoidance of infection by properly caring for sputa and by other disinfection. The plans of the Pennsylvania Society were presented by Dr. L. F. Flick. These are: (1) Education of the people by tracts, etc. (2) Registration of diseased human beings and animals. (3) Establishment of hospitals for advanced cases and sanatoria for incipient cases. Dr. J. C. Wilson read a paper on "The Necessity of Hospital Care for the Consumptive Poor." Hospitals are established for other contagious diseases, incidentally for the good of the individual, but primarily for public protection. Provision should be made for the consumptive also and the establishment of special hospitals and sanatoria is the solution of the problem. Patients should not be sent to them on commitment, but voluntarily. Sentimental difficulties will lessen as the plan is carried out. The arrest of the earning power of the individual is important, but some could still work in the sanatoria.

Dr. Guy Hinsdale spoke of the "Localities Suitable for the Treatment of Consumption in Sanatoria throughout Pennsylvania." Places where climatic conditions are most favorable are at Glen Summit and White Haven, in Luzerne county, 1250 feet elevation; the Pocono region in Monroe county, 1800 to 2100 feet elevation; Kane, in McKean county, 2000 feet elevation and one of the coldest and dryest parts of the State, and Cresson, in Cambria county. This has the same elevation as Kane and is already a summer resort. Dr. E. O. Otis advocated the establishment of city hospitals and sanatoria. Several hospitals would be needed for a city like Philadelphia. Voluntary applications would fill many hospitals. For others, make consumption a notifiable disease. It is a mercy to the poor consumptive even if it is against his will. Dr. J. M. Da Costa considered that the community owes more to the consumptive now since his lot had been made harder by the scientific discovery that consumption is a contagious disease and thus bars him from the general hospitals. For this reason it is doubly the duty of the medical profession to come to the rescue of these sufferers.

CHICAGO.

State Sanatorium.—At a meeting held January 10th, the State Board of Health unanimously recommended the establishment in Illinois of a sanatorium for consumptives.

Smallpox.—There have been reported to the State Board of Health during the past quarter over five hundred cases of smallpox, the disease occurring in seventeen counties. There were five deaths from the disease in Alexander, Lee, and Williamson counties.

Dr. N. S. Davis.—The father of the American Medical Association celebrated the eighty-third anniversary of his birthday on January 9th. Dr. Davis is still well and active. He spent most of his leisure time receiving congratulations from professional and other friends.

Osteopaths Fight.—The osteopaths of the State will make an effort to test the medical practise act passed by the last Legislature, because at the instance of the State Board of Health it is said that three arrests have been made, and the parties so arrested promise to bring suits for false imprisonment.

School Inspection.—Reports for the first day's work of the medical inspectors of public schools revealed more than a score of children suffering from scarlet fever in the desquamative period. These children were sent home, to remain there until danger of contagion has passed. This revelation shows that the appointment of the inspectors was justified.

Officers of the Chicago Ophthalmological and Otological Society.—At a meeting, held January 9th, Dr. C. D. Wescott was elected president, Dr. Casey A. Wood, vice-president, and Dr. C. P. Pinckard, secretary-treasurer. The membership committee consists of Drs. Wilder, Ware and Coleman. Dr. William E. Gamble showed a case of interstitial keratitis, and Dr. Oscar Dodd one of quinine amblyopia. Dr. J. E. Colburn reported a case of methyl alcohol poisoning.

Sand Filtration.—The committee appointed by the State Board of Health to investigate the water supplies and sewage systems of cities on Lake Michigan, north of Evanston, in its report recommend that the cities adopt slow sand filtration as a means of purifying their water supply, which is known to be polluted. The report was accompanied by an analysis of the water of Lake Michigan at Highland Park, made by Professor J. H. Long, which showed the water to be polluted.

Abolition of the Board.—It is said that the homeopaths and eclectics of Illinois are organizing to fight the medical practise act, passed by the State Legislature last year, making the State Board of Health a Medical Examining Board. Their aim is to have this act repealed during the coming session of the State Legislature, and to abolish the State Board of Health in its present form, substituting for it a Board of Sanitation, whose members shall be chosen as are other State officials.

Vital Statistics.—The mortality for the first week of the new year, as shown by the weekly report of the Health Department, was in excess of the preceding week, and 19 more than for the corresponding week of 1899. The excessive number of deaths at the present time is declared to be due chiefly to the prevalence of the acute respiratory diseases, pneumonia and bronchitis. These two diseases are alone responsible for 25½ per cent. of the total mortality, there being 91 deaths from pneumonia, and 41 from bronchitis. The mortality from diphtheria during the week was in excess of that of any week during the past year, there being 28 deaths from this cause, as compared with 27 the week previous, and 18 the corresponding week of 1898.

Fixation of the Stirrup.—Dr. J. Holinger read a paper before the Chicago Pathological Society on this subject, in which he drew the following conclusions: (1) The fixation of the stirrup is due to abnormal growths of spongy bone in the bony capsule of the labyrinth. (2) This growth has its primary seat in the surroundings of the oval window. It may spread over other parts of the labyrinth by continuity. (3) Besides a simple enlargement of the foci, independent, circumscribed foci may be found in other parts of the labyrinth. (4) The spongy bone outgrows the normal labyrinth, forming osteophytes in the middle ear, the vestibulum, into the oval window and its niche. (5) The stirrup thus becomes fixed or even luxated, being pushed away from its normal position, and becomes ankylosed in an abnormal position. (6) Microscopically the bone corpuscles are large and clumsy. The perivascular and perineural spaces are filled with bone. In the open spaces of the spongy tissue connective tissue is found.

GENERAL.

Professor Chittenden Ill.—Director Russell H. Chittenden of the Sheffield Scientific School was reported, on January 16, to be seriously ill with typhoid fever. Professor Chittenden is one of the foremost authorities in physiological chemistry and bacteriology in the world.

Influenza in Europe.—Last week we mentioned the serious epidemic character of influenza which was raging in London. Telegrams from Berlin announce that it is now rife in that city, and that scores of deaths from that cause are already reported. Barcelona, Spain, also reports the presence there of the influenza.

Professor Atwater Controverted.—In a pamphlet entitled "An Appeal to Truth," a committee appointed at the Northfield (Mass) Summer Conference of Christian Workers of 1899 has presented scientific evidence to the effect that Professor Atwater's costly experiments have produced nothing to sustain his charge of error against the present temperance teaching that alcohol is not a food but a poison.

Device to Identify Babies.—The physicians of Johns Hopkins Hospital have devised a plan to prevent the "mixing-up" of the newly-born in the obstetrical wards. A square of water-proof adhesive plaster, on which is written the baby's name, is applied tightly between the shoulder blades. This remains secure until the baby and its mother leave the hospital, when it is pulled off without giving the infant pain.

The Dum-Dum Bullets.—It is reported from London that the Lee-Metford cartridges are running short in the British magazines and the War Office purposes falling back temporarily upon 100,000,000 "Mark IV." expanding bullets, most of which are already in storage in South Africa. The War Office, however, has issued strict orders to the volunteers now in England that the fifty rounds of "Mark IV." given them must be used in practise at home.

Dead Animals in the Paris Streets.—A most extraordinary sanitary regulation has recently gone into effect in Paris. Formerly there were no facilities for removing dead animals from the streets and they were left to decompose in the sun and rain. The prefect of police has inaugurated a scheme by which such nuisances may be removed on application by any citizen. The applicant, however, is obliged to stand the expense of removal, but the cost is not to exceed $1.

Farms for Consumptives.—A project is about to be launched in Colorado which is apparently of

more value in the treatment of consumptives than anything that has heretofore been offered. It is proposed to establish from Denver south a series of plantations, which shall be under State control, but so far as possible will be made self-sustaining by the labor of their inmates. These are to be opened to those consumptives who can afford the price of transportation.

Hospital Cruisers.—The latest suggestion in the crusade of trained nursing comes from the Colonial Nursing Association of London. It proposes to fit up hospital cruisers, supply them with dostors and women nurses, and send them out to the tropics, where they can cruise about and instruct the natives, at points where they touch, in the art of nursing, the establishment of hospitals, etc. The expensive equipment of hospital ships would not be required in these cruisers; it is not their purpose necessarily to follow the ravages of war, but to go to peaceable settlements.

Obituary.—After an illness of two days Medical Inspector Charles A. Siegfried, U. S. A., died January 14th, from consumption, at his home in Newport. Inspector Siegfried was a graduate of Jefferson Medical College and took a post-graduate course in Germany and at the Johns Hopkins University. During the war with Spain he had charge of the Naval Hospital at Key West. He leaves a wife, who was Miss Farrel of Peoria, Ill., and a cousin of the late Robert Ingersoll.—Dr. William H. Lyons died at his home, New York City, January 13th. He was a graduate of the College of Physicians and Surgeons and had been in active practise for twenty-five years.

Death of Dr. Axtell.—Simultaneously with the publication of an article by Dr. Edwin R. Axtell of Denver, Col., which appears in this issue we are grieved to announce his death, which occurred at his home, December 14, 1899. His death was due to a virulent streptococcic infection incurred during the performance of a post-mortem examination, December 1st, upon a subject dead of sepsis, at the County Hospital. Dr. Axtell was 33 years of age. He had been especially interested in bacteriology and pathology, and had recently been appointed visiting physician to the County Hospital. He had just reached the point where, having laid a magnificent foundation by the devotion of twelve years to the study of the fundamentals of medical science, he was about to enter upon clinical work. He gave promise of a brilliant career.

Nursing in Ladysmith.—A nurse, who went to Ladysmith October 28th, and afterward accompanied the wounded to Durban, vividly describes some of her experiences in the *Hospital Nursing Mirror*. "We were operating, amputating, all Tuesday night and they were dying all around us. I washed twenty men all alone. Some were put under the X-rays for the bullets. Many nurses had narrow escapes. During Monday the enemy kept shelling the town, and a shell fell right at Nurse M.'s and my feet. On Wednesday the twenty-four hours' truce was over which was granted by General White to the enemy to bury their dead and attend to the wounded. We were all up and ready for the Boers to shell the town and on one who was not there can ever imagine what we felt like when 'Long Tom' began to fire; our own guns were not in position then."

Malaria Eradication.—The English Malarial Expedition, with the hope of eradicating malaria in its native districts, recommends that the haunts of the malaria-bearing mosquito should be destroyed or rendered uninhabitable by the larvæ of that insect. The German expedition to Italy, acting upon the theory that the cycle of sexual reproduction is completed only by a sojourn of the plasmodium in the blood of man, recommends that all people living in malarial districts should be treated efficiently with quinine during the period that the plasmodium is confined to man as its only host. If the parasites can live outside the human body only in certain species of mosquitoes and during the hottest months, it follows that for about eight months of the year they are confined to man. It is during this time, the committee believes, that the malarial parasite of any given neighborhood may be absolutely destroyed by treating all the patients with quinine. This committee finds that a second variety of mosquito, the *calex pipiens*, as well as the *anopheles*, acts as a host of the malarial plasmodium.

The Merciful Mauser.—Sir William MacCormack, the President of the Royal College of Surgeons, who has volunteered his services for the South African war, has related in a letter to the *Lancet* his first experiences with wounds inflicted by the Mauser bullet. The external wound produced by it is small. In three-fourths or more cases it was impossible to tell the exit from the entrance wound, so similar were they in appearance. Some were quite healed, but most were slits covered with an adherent black scab, slightly depressed and saucer-like. The size was much smaller than the end of a lead-pencil and quite circular. A few exit wounds were slits, due to slight deflection in the passage of the bullets. These were healed like incised wounds and showed a linear cicatrix about half an inch long. Probably most of the injuries examined were inflicted at a range of 1000 yards. Sir William noticed a number of bone perforations without any solution of continuity or complete fracture; in one instance there was such a perforation of the shaft of the tibia at the junction of the upper and middle third. There were several cases in which the bullet had entered the groin and had emerged through the central portion of the buttock, the direction taken making it difficult to conceive how the femoral vessels, the sciatic nerve and artery, the femur, and other important parts had escaped all injury. Several cases of abdominal injury with recovery without laparotomy were noted. Seventeen very interesting

cases are briefly described, most of which are characterized by quick recovery.

The Plague.—It is reported from Manila that two more cases of plague have appeared there. The authorities seem to have the matter well in hand, however, and all danger of an epidemic is very remote. The health authorities at Adelaide, South Australia, report January 14th two cases of bubonic plague there, one being fatal.

At Honolulu twenty-two deaths from bubonic plague have been reported up to January 9th. Practically every case has proved fatal, but four cases now in the hospital promise recovery. About two thousand persons have been removed from the infected quarter, and are now herded in quarantine camps. New cases are constantly appearing at points distant from the original center of infection, showing that the germs of the disease have been widely scattered. The Council of State has appropriated $20,000 for a garbage crematory, and $250,000 with which to put the city in a sanitary condition.

The lifting of the quarantine on Chinatown just before Christmas is thought to have been responsible for the fresh outbreak of the disease. On December 31st it was decided to destroy all infected houses. Since then five sections of Chinatown have been destroyed. Two sections were burned recently. One of these included the principal Chinese Joss house in the city, where a Chinese was found sick with the plague.

In the meantime a house-to-house inspection is going on, especially in the Asiatic quarter. This inspection has revealed several cases of leprosy that had escaped the vigilance of the authorities.

C. F. Reynolds, Executive Agent of the Board of Health, who has been most active in the work of fighting the plague, has been taken sick and is believed to have the plague.

The fear of the plague at Tokio, Japan, has led to a general housecleaning of the city. Every house and hovel within its hundred square miles of area is being cleansed under police supervision, and the streets are piled with rubbish heaps. Not only the mats, but the floors are removed and the accumulated débris of years is being swept away.

The number of deaths, largely from the bubonic plague, jumped up, at Bombay January 12th from 282 to 376. The normal death-rate is 75.

The bubonic plague has made its appearance at Rio Janeiro, as shown by the following cablegram received January 11th by Surgeon-General Wyman of the Marine Hospital Service.

"There has been one death from plague at Rio Janeiro. This diagnosis confirmed by bacteriological examination."

MEDICAL JOTTINGS FROM TROPICAL COUNTRIES.

Specific Cuban Fever.—Dr. Thomas B. Coronado, in an article on "Our Fevers," which appeared in a recent number (No. 421) of the *Anales de la Academia ciencias medicas, fiscas y naturales de Habana,* discusses the various fevers that occur in Cuba. All of them come under the head of some of the ordinary infectious fevers—yellow fever, or typhoid, or la grippe, or dengue, or malaria. There is no such thing as a special form of febrile disease running a course peculiar to itself and causing anatomical lesions that can be differentiated from these well-known affections. The term "Cuban fever" usually means malarial fever of the remittent type. A combination of typhoid and malaria, a typho-malarial fever, is reported rather frequently in Cuba, but it is probable that it is of rare occurrence, and that the cases seen are anomalous types of either disease.

Pathogenesis of Yellow Fever.—This is the title of an article read by Dr. M. S. Iglesias before the National Academy of Medicine of Mexico and published in the *Gaceta Medica* of Mexico, November, 1899. Dr. Iglesias has been able to secure all the details of the histories of 127 cases of yellow fever that occurred in Vera Cruz during the epidemic of July, 1898. A careful collation of the details of these histories seems to him to bring out the conclusion that water is never the means by which yellow fever is distributed. It also seems to bring out the fact that the micro-organisms which cause the disease find their way into the system through the patient's lungs; that they multiply in the pulmonary alveoli, producing the toxin which after absorption cause the constitutional symptoms of the disease. It is in the lungs and not in the blood, the liver, or the digestive tube of the patient that the microbe of the disease must be sought, although so much fruitless work has been done in the investigation of these latter organs post-mortem, while the lungs have usually been entirely neglected.

Beri-Beri.—Sporadic cases of beri-beri have become so frequent in the seaport towns of this country that the question of the micro-organism of the disease has become an interesting one for American medical men, or at least those who live along the coast. Scheube, in a critical review of the subject of the etiology of beri-beri in the *Archiv f. Schiffs und Tropen Hygiene,* not long ago, declares that all the supposed pathogenic agents which have so far been discovered by observers and announced as the specific cause of this curious disease have had but an ephemeral reputation in this regard. He considers that the organism is still to be discovered. Somewhat more than a year ago Dr. Francisco Fajardo of Brazil, in a communication to the National Academy of Medicine of that country, presented an article to that body on the etiology of beri-beri, and demonstrated a series of preparations in which he thought he was able to point out the microbic cause of the disease. The parasite is a hematozoon and is not unlike the parasite which causes malaria. The new hamatozoon, which it is proposed to call the methematozoarium Fajardi, is not affected at all by quinine. This constitutes

the main difference between the two parasites. As the result of Dr. Farjaro's demonstrations the new parasite was accepted by most of the members of the Academy as the real cause of the disease. Dr. Miguel Pereira, in an article on the subject in the *Revista Medica de San Paulo*, confirms Dr. Fajardo's conclusions and announces that he has been able to find in fresh preparations of blood drawn from the peripheral circulation of patients suffering from beri-beri a corpuscle of oval form containing pigment with an appendix at one of its poles, as if it were on the point of sporulation. Dr. Fajardo, to whom the preparations were submitted, identifies the specimens as one of the forms of the hematozoarium which he described.

Wintergreen in Chorea.—So much has been written about the connection between chorea and rheumatism that it is a little surprising that the presumedly specific remedies for rheumatism have not been more frequently used in the disease. In a series of cases in France it has been found that oil of wintergreen was a very efficient remedy for this affection; that it often gave satisfactory results where the ordinary medicaments recommended for the affection failed. From 45 to 75 grains of the drug were given daily, although more than this has been used in certain cases. The remedy has been tried with success in Brazil, according to a recent number of the *Revista Medica de San Paulo* and it would seem that a new remedy for this affection, which often proves so obstinate to treatment, has been found.

Contagiousness of Plague.—Dr. Victor Godinho, one of the editors of the *Revista Medica de San Paulo*, in an article, written before the occurrence of any plague cases in Brazil, calls attention to the different methods by which plague is propagated. While the favorite method would seem to be inoculation under the skin or through the mucous membrane of the mouth or the digestive tract, Dr. Godinho points out that in many cases that are always of the fatal type the infection takes place through the lungs. All three of the cases he recalls that occurred in Vienna were of this pulmonary type. He thinks that transmission of the disease through the air is very common, and he argues therefrom the necessity for the greatest caution in their commercial relations with Portugal, and especially with Oporto, as the introduction of the disease into South America will probably give rise to a severe epidemic. This ominous foreboding before the event is all the more striking now that we know that the disease has gained a foothold at Santos, and perhaps even at San Paulo itself, and that Dr. Godinho's prophecy is being fulfilled. The eradication of the disease is proving to be anything but an easy task.

Drs. Pryor and Dillon Brown of New York, both of whom have been having a serious struggle with typhoid fever, and have occasioned great anxiety among their friends in the profession, are reported as improving.

CORRESPONDENCE.

THE "BAREFOOT CRAZE"; A LETTER TO HIS "GRANDMOTHER"—THE WORLD.

My Dear Grandmother:—I have a confession to make, and one that you would hardly believe possible, in view of my strong advocacy of late years of a certain new doctrine. While we differ markedly in some respects, still in the matter of our "natural instincts" we are very much alike. Our instincts are simply our inheritance from our ancestors, inheritance of beliefs, notions, or whatever we may chose to call them. My confession is that in spite of my practise of having my children go barefooted, not only in summer but even throughout the winter indoors, with no objection to a brief run in the snow for that matter, still my first impression, that is my instinct, is precisely like your own; there is a sort of cringing feeling comes over me every time I see them outdoors barefooted in the wet, cold grass of a November morning. Hence I am able to fully sympathize with you, dear grandmother, when you shudder and feel inclined to "roast" me for my cruel treatment of your great-grandchildren. But the fact of it is, my *reason*—and herein, by the way, lies the difference between instinct and reason; the latter can be modified by evidence, while the former is like the color of our eyes, or hair, constitution, temperament, etc., practically unchangeable—my *reason* has been convinced by an amount and quality of proof that cannot be controverted; hence I am compelled to smother my instinctive feeling inclining me to save my little ones from the alleged dangers arising from going barefoot. This, you dear old soul, is what you cannot possibly do; for you have only your instinct in this matter to guide your feelings, and it is more than doubtful if you are really willing to put your mind in an attitude to candidly consider the great array of evidence furnished by numerous intelligent and studious witnesses who have, like myself, been forced to put instinct aside and listen to reason.

On a cold October day, a dozen or more years ago, the passengers on a train running out of Baltimore were shocked to see a ten-year-old boy leap out of the car and run along the platform barefooted. When the train was about ready to start the lad re-entered the car and joined his friends, a mother and sister, both elegantly dressed and evidently belonging to the "higher class." Indignation among the good people who witnessed this extraordinary sight ran high, naturally enough. It was not that these onlookers were what we could properly call ignorant people, but the way in which they acted on this occasion clearly proved their ignorance in this particular matter. However, before this little group of happy people was outraged by any marked demonstration of the ignorance and brutality of the mob, a newspaper man who chanced to be on the train, thinking more of an item for his paper and of his own income than

of the boy's danger of dying of pneumonia before reaching Washington, approached the ladies and in a most respectful manner, apologizing for his action, begged for an explanation which was very amiably given. The elder one of the party was the wife of Dr. ——— of Baltimore, a fashionable regular, and the young lady and the barefooted boy were their children. It seems that the first three children of this couple died of diphtheria, although they had been very carefully shod, stockinged, and in all ways treated according to the conventional views then as now prevailing. By the time of the advent of their fourth child, the father had heard something about the Father Kneipp "Barefoot Cure," and upon careful investigation and study of the anatomy and physiology and hygiene of the question he became convinced of the fact that his care for his first children had been mistaken, and he adopted a radically different plan, especially in the treatment of the new baby's feet. It seemed to work quite satisfactorily. The baby had fewer "colds," as these well-known but much misunderstood attacks are commonly termed, and in all ways grew more robust than its predecessors. They now had three children, the eldest a young woman, the ten-year-old boy, and another boy between the two in age. All three had been kept barefooted, winter and summer, throughout their childhood, *using* not *abusing* shoes and stockings—that is wearing them when required for protection against snow and severe cold, and, upon occasion, for style! The story spread rapidly among the passengers, and thus a scene was prevented.

Within the past seven or eight years a member of the family of the late Premier of England, Gladstone, has had the benefit of the barefoot cure. Little Dorothea Drew, Gladstone's granddaughter, was a puny child; they heard of the Kneipp treatment, or perhaps it was their family doctor who first became a convert and prescribed the treatment. At any rate, she was given the benefit of the method, and she went barefooted winter and summer, outdoors and indoors, except outdoors when there was snow or cold mud. By this means and a restricted and improved diet she grew into a hale, hearty child. I think I have mentioned this pregnant fact before but it will bear repeating over and over again and ought to be printed and spread before the people until the lesson shall be generally comprehended.

Here is another item of evidence and from a "reluctant witness"—the kind that is in law declared to give the most convincing testimony: Dr. Thomas, a regular, and for many years with the missionaries in Turkey-in-Asia, some years ago contributed an article to the *Medical Times* on this topic, in which he told how it used to "break his heart" to see the children of both rich and poor going barefoot all the year round, these bare feet often blue with the cold; "but," he says, "as the time rolled along, year after year, and I could observe no ill effects from the practise, but, on the other hand, an absolute exemption among the native children from croup and diphtheria, I became quite reconciled to the practise. In eighteen years I was never called to attend a case of croup or diphtheria."

You see, dear grandmother, how much pains I am taking to convice your mind in this matter, so that your declining years may not be made wretched at the sight of your precious grandchildren clipping about the house and grounds with feet which (barring accidents) smell as sweet as their hands, feet that are physiologically clean, instead of being penned up in their filthy secretions to aid in the production of the various filth-diseases, from ordinary "colds" to the more fatal disorders, measles, scarlet fever, pneumonia, diphtheria, etc. If only you can be convinced of the truth of this matter and thus enabled to help educate others, instead of standing ready to aid and abet the ill-informed gossips who do so much to check all progress along hygienic lines, much good would arise from it, and you would experience a new and delightful sensation at finding yourself in the van of progress, instead of hanging on behind, so to say.

Evidence such as I have herein given you could be multiplied and volumes of proof furnished to show the correctness of my claim, but it could add nothing to what has already been offered, and I imagine that you have now as much as you can digest and assimilate, and I do not wish to weary you.

Your affectionate grandson,
Charles E. Page, M.D.

154 Tremont St., Boston, Mass.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, January 6, 1900.

HIGH DEATH-RATE IN LONDON—TWENTY-TWO INFANTS SUFFOCATED—WELSH WATER FOR LONDON—CHRISTMAS AT THE HOSPITALS—OVERCROWDING AND HIGH MORTALITY IN KENSINGTON—MUNICIPAL "ECONOMY" IN SANITARY MATTERS—WATSON CHEYNE GOES TO THE FRONT—TWO HUNDRED MEDICAL STUDENTS VOLUNTEER AS DISPENSERS—CONVALESCENTS FROM DURBAN RETURNING TO ACTIVE SERVICE.

The death-rate in London last week showed a continuation of the heavy rise noted in our last letter, due to the combination of snow and fog. The high figure of 23.8 per 1000 was reached, the climax so far of a rapid upward climb from hardly above 17 per 1000 of some five weeks ago, last week's being 22.4. The lion's share, as usual, both of actual deaths and increase, falls to diseases of the respiratory organs which caused no less than 646 out of the total of 2078, or about 32 per cent. This huge number is 208 above the corrected average for this week of the year.

There is also uncomfortable evidence that the smallpox epidemic at Hull is far from being

checked, as twelve deaths are reported, but only one other in all England and Wales by this disease.

A startling item to Transatlantic eyes is the number of deaths of infants from suffocation in bed, which stands at the appalling figure of twenty-two in one week. These are due chiefly to two factors, overcrowding and alcoholism, parents rolling over upon their offspring in the heavy slumber of drunkenness. It is said that most of these distressing accidents occur upon Saturday nights, after the "pay-day" carouse.

The London County Council, undiscouraged by its previous experiences of the hardness of heart or thickness of head of the average member of Parliament when sanitary matters are to the fore, is again preparing a Water Supply bill to come before the next session. This is a broad and far-seeing measure providing for the securing of collection-basins and reservoirs in the Welsh mountains and the construction of aqueducts to connect these with London. It is a colossal project, as its estimated expense, $90,000,000, would faintly shadow forth, but it would be one of the best investments imaginable for the metropolis for years, indeed centuries, to come. From a hygienic point of view this goes without saying, but it would be so from a financial, if past experience is any guide. A single "Founder's" or "Adventurer's" share in any of the old waterworks companies of London is now a small fortune in itself. One recently put up for public sale had an advertised income of over $20,000 attached to it, and it was described and handled as if it had been a ducal estate, fetching finally a fabulous sum. Nor are their golden days over even yet, for the Welsh scheme will take at least fifteen years, after the expenditure has been authorized, to open up the first line of communication.

Christmas was celebrated at the hospitals with the usual kindly and cheering festivities, with turkeys, game and mince-pies for dinner, dessert and "smokers" in the afternoon and conjuring and dramatic entertainments in the evening. It is estimated that not a single patient in all the London wards failed to receive at least one present, so that there are evidently many worse places in which to spend Christmas than the great hospitals.

A distressing exception to the usually high standard of sanitation maintained in London has just been made public in the report of the Special Inspector, Dr. Hamer, upon the condition of Kensington, one of the wealthiest parishes in the West of London. It is the old Court Suburb and takes its name from the Royal Palace, in which Queen Victoria spent her childhood. In the area specially reported upon, the overcrowding is scandalous, eleven houses in one street containing 252 inmates, eight houses in another street, 238, and twenty-three common lodging-houses sheltering every night an average of 622, or nearly thirty each. So that we can hardly be surprised to hear that the death-rate of this district stood in 1898 at 45.5 per 1000, more than double the general London rate. The chief excess was in the infant mortality. As usual, this condition of affairs has come about by the persistent disregard, on the part of the Vestry, of the urgent recommendations of the district medical officer, Dr. Dudfield. His requests for an increase of the sanitary staff were refused on the ground of expense, but, as Dr. Hamer, in summing up severely remarks, the outlay to which they have been put in connection with sickness, quarantine and death, has been far greater than that which would have been needed to bring the sanitary staff up to an effective basis. To say nothing of the suffering, notoriety and disgrace incurred.

Another leader of the profession has volunteered for service in South Africa. Watson Cheyne, the well-known surgeon and surgical pathologist of Kings College Hospital, is to start at once accompanied by Mr G. Cheatle and Mr. F. A. Hadley, house-surgeon. This makes the third of the great London hospital schools to be represented at the front by the chief surgeon; St. Thomas's, by Sir William MacCormac; the London, by Mr. Fred. Treves, and now Kings, by Watson Cheyne. Scores of the younger men are most anxious to go and a batch of seventeen are being sent out by one transport this week.

A few days ago in Edinburgh a call was issued to the medical students for volunteers for the Army Medical Corps as dispensers. Even for this necessary and useful but not particular exciting service the response was most generous, no less than two hundred men presenting themselves as volunteers. A number of offers of service were also received by telegraph from students absent on their vacations. Only three days later the first squad of those selected were ready to depart for Aldershot, *en route* for the Cape.

Sir William MacCormac praises most highly the efficiency of the ambulance corps at the front, both army and volunteer. No less than 800 wounded have passed through Chievely Field Hospital, and all requiring attention were removed from the field of battle by five o'clock in the evening. The base hospitals seem to be doing equally good work, as several detachments of convalescents have already returned to service at the front, completely restored by their short stay in the sea-air and under skilful nursing and attendance on the hospital ship "Lismore Castle," anchored off Durban.

THE SCIENTIFIC BASIS OF ORGANOTHERAPY—THE PRACTICAL RESULTS OF ORGANOTHERAPY—ACTINOMYCOSIS OF THE KIDNEY—POISONING BY URINE—CARCINOMA OF THE LARGE INTESTINE.

At the Berlin Medical Society, Nov. 8th, A. Loewy and F. F. Richter read a paper upon the scientific basis of organotherapy. They de-

scribed organotherapy as a method of substitution, by which some substance lost to the body is replaced. As the most striking example of this method of treatment they mentioned thyroid therapy. By the removal of the thyroid the organism suffers and certain symptoms develop which may entirely subside if thyroid glands or thyroid extracts are ingested in sufficient quantity. The conditions after the removal or resection of the spleen, kidneys, suprarenal capsule, pancreas, or regenerative glands are not so easily understood, since the physiological effect of these organs upon the rest of the body is not at all known. That they have a marked influence, however, is shown by the changes which take place even in the skeleton after the removal, for example, of the ovaries or testicles in early life. There is also a change of metabolism produced by castration which can be scientifically studied in the case of animals. The writers then described in detail the results of their investigations along these lines, stating that the ingestion of ovaries restored metabolism to normal in animals and in women whose ovaries had been removed. They also expressed the hope that oophorin-therapy will be successful in relieving the symptoms of chlorosis, a disease due, according to their theory, to insufficient action of the ovaries.

In the discussion of their paper, Ewald said that the theoretical views advanced by the authors were not sustained by the practical results which, in his hands, followed the administration of ovarian extract. He has given oophorin in a great many instances; sometimes to women in the climacteric, sometimes to young girls suffering from imperfect menstruation. In certain cases the results appeared favorable, but in many more no good result could be observed. He therefore expressed himself as skeptical regarding the remedy, which at best acted in a very unsatisfactory way, and said he considered that the good improvement was due to suggestion, or was merely a coincidence.

Landau has also given oophorin to many women who suffered from the symptoms of an artificially produced climateric, whether as a result of operation or disease. He expressed himself as being in general much pleased with the results obtained, although he admitted that they were by no means so certain as those which follow the administration of quinine in malaria or mercury in syphilis.

Virchow said that it is a most uncertain method to grind up a whole ovary and give it as medicine without knowing to what portion of the structure any possible result which may follow is to be attributed. The amount of the specific cells contained in an ovary is so slight that it is difficult to imagine that they can possibly produce the striking results said to follow the administration of ovaries. When one goes further and asserts that a transplanted ovary can live in its new situation and manufacture whatever special secretion the normal ovary produces, he is spinning a tale which belongs to the "Thousand and One Nights." When one considers what differences of opinion there are with reference to the therapeutic effects of so comparatively simple a substance as serum, there is evident need of further knowledge of the active principle of such a complex organ as an ovary before one discusses the therapeutic effects of oophorin.

Pinkuss said that it is necessary to know the patient before drawing conclusions as to the effect of oophorin treatment. Hysterical women and women who have suffered severely from chronic inflammatory troubles before their operations may improve after the administration of oophorin, but such improvement can well be due even to suggestion or to the removal of the diseased organs. At the last congress of gynecologists the advisability of leaving the whole or a portion of one ovary was thoroughly discussed. Most of those who heard the discussion came to the conclusion that it is absolutely a matter of indifference whether one ovary is left or not. Some women after castration present the symptoms attributed to suppression of menstruation, while others do not.

Hansemann called attention to the differences which probably exist between glands of different animals. Thus the thyroid of a sheep and the thyroid of another animal may have similar functions, but their extracts are probably neither exactly alike nor like that in the thyroid in man. Under such circumstances it is not to be expected that the results obtained by the administration of thyroid tablets will be in all cases similar.

At the meeting of November 29th, J. Israel showed an actinomycotic kidney which he had taken from a man aged thirty-three years. The patient had hematuria, especially after violent exercise, for seven years. Two years after the beginning of the trouble his kidney was opened for the removal of stone, but none was found. The organ was found adherent by its upper end, but was left *in situ*. The patient did not improve, but grew weaker and lost flesh and strength, while the fistula leading into the kidney never closed. An exploratory operation was therefore performed, and as the substance of the kidney was found to be thoroughly degenerated, the kidney and fistulous tract were removed. Microscopical examination of the contents of the cyst showed the presence of antinomycosis.

Posner discussed the poisoning by urine at the meeting of December 6th. Experiments which have been cited to prove the poisonous qualities of urine are open to serious criticism. The injection of great quantities of fluid is not without danger, while too little attention has been given to the osmotic effect of the injected fluid, and to the general condition of the animals experimented upon. In his own experiments he used white mice and injected subcutaneously urine of such concentration that its freezing point was identical with that of blood serum. It has been found that solutions having the same freezing point as serum are osmotically indifferent, and

do not irritate the tissues when injected into them. Distilled water will kill a mouse if injected into his tissues. A solution of salt 0.9 or 1.0 per cent (not 0.6 per cent., as usually supposed) is absolutely indifferent and is the real normal or physiological solution. Urine having the freezing point of serum produced little more effect when injected into mice than did the physiologic salt solution. It would be going too far to conclude that urine has no poisonous quality, but the poisoning in uremia is certainly not explained by injection of urine into the tissues.

At the Union for Internal Medicine, November 27th, Boas gave his experience with carcinoma of the large intestine. He has seen fifteen patients, three of them women. In six cases the site of the tumor was the cecum, in four the sigmoid flexure. In certain cases the subjective symptoms are so slight that the diagnosis cannot be made; in other instances there is obstinate constipation or severe colicky pains with nausea and vomiting. In such instances the carcinoma is of a circular form. Sometimes the first suspicion of the tumor is aroused when intestinal obstruction occurs. Tumors in the cecal region must be differentiated from tuberculosis and inflammatory products the result of appendicitis. Medical treatment consists in keeping the bowels open. Twelve of the fifteen patients observed came to operation. Resection was performed five times, with three deaths; entero-anastomosis four times without appreciable improvement. In most instances the operation was performed too late. A favorable symptom for operation is mobility of the tumor while the patient is still strong. A symptom necessitating operation is stenosis of the intestine. Enterostomy and colostomy are only to be performed in case obstruction is imminent.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.—SECTION ON MEDICINE.

Stated Meeting, Held December 19, 1899.

Louis Fougères Bishop, M.D., Chairman.

Heart Sounds.—Dr. Lewis A. Conner read a paper on the relative intensity of the second sounds at the base of the heart, that had been written by Dr. Sarah R. Creighton. Practically all the text-books thus far have taught that the second sound of the heart at the pulmonary cartilage is less in intensity than that at the aortic cartilage. The theoretic explanation was supposed to be that as the tension in the systemic circulation is much higher than that in the pulmonary circulation, the snap of the aortic valve is sharper and more audible than that of the pulmonary valves. Professor Gerhardt of Berlin alone teaches that the sounds of the aortic and pulmonary valves are of equal intensity. Holt says that in children, at least, the pulmonary sound is more intense than the aortic. Years ago Vierordt demonstrated, by pasting pieces of rubber adhesive plaster over both the pulmonary and aortic areas until the sounds at each were obscured, that the pulmonary sound was practically always more intense than the aortic. It is only after the age of forty that the aortic sound becomes the more intense of the two. Mueller repeated Vierordt's observations, but did not get the same result. Schryver, however, who worked with Mueller, confirmed Vierordt's observation. The subject deserves further careful investigation.

In a thousand patients in Dr. R. Cabot's clinic, all of them without heart lesions, 291 had the pulmonic sound more intense than the aortic. In 233 the sounds were equal, while in 476 the aortic sound was more intense. Under ten years of age, 90 per cent. had accentuation of the pulmonic sound; between ten and twenty over 60 per cent; between twenty and thirty, about 33 per cent; between thirty and forty, only 13 per cent; between forty and fifty, 14 per cent. The accentuation of the aortic sound becomes more marked with each decade of life. While most of the persons were under treatment for some affection or other all of them could walk to the clinic and were in reasonably good health. Many were assistants and friends accompanying patients. In children, according to Rotch, the lungs are not fully expanded until the fifth or sixth year, or perhaps, even later. It is probable that this fact has something to do with the accentuation of the pulmonic second sound so constantly found during the first decade of life.

Conclusions.—Pulmonary accentuation is invariable in childhood, is frequent in youth, becomes about equal in intensity with the aortic sound between twenty and thirty years of age, while after this aortic accentuation is the rule. It is evident that if the pulmonary accentuation is to be judged in any given case it cannot be decided by comparison with the aortic sound, but the criterion must be the memory of a normal sound.

Accentuation of Pulmonary Sound.—Dr. Emily Lewis said that the accentuation of the pulmonary second sound in children is only apparent. During infancy and adolescence the heart hangs more vertically in the thorax and so the pulmonary valves are much nearer the pulmonary cartilage than are the aortic valves to the corresponding cartilages. This has been proven by actual observation in Simonton's frozen sections on the other side. In addition these sections show that while the left pleura hardly comes to the left edge of the sternum the right pleura comes well over to the median line. The pulmonary valves are much less covered by pleura than are the aortic valves, and consequently the sound made by the closure of the valves is heard more distinctly. Percussion shows that the heart in children is more to the left of the sternum than it is in the

adult and relative heart dulness on this side of the sternum, even above the third rib, is not uncommon. A certain number of the patients examined by Dr. Creighton were suffering from anemia and in these cases it is almost always the rule to find an accentuation of the second pulmonary sound. This would undoubtedly prove a source of error in the statistics and somewhat lessen the force of the conclusion that even in young people the second pulmonary sound is always more intense than the corresponding aortic sound.

Dr. J. K. Crook pointed out that the pulmonary second sound is much more responsive to alterations in the pulmonary circulation than the aortic sound is to changes in the systemic circulation. Even exercise and excitement affect the pulmonary sound more than they do the aortic. The excitement of a simple medical examination is often sufficient to cause quite a variation in the intensity of the pulmonary second sound. The second sound as heard in the pulmonary area is of great prognostic value in lobar pneumonia, so that the discussion as to its exact intensity in normal conditions is calculated to be of the greatest value. In pneumonia the pulmonary sound is always accentuated. When it begins to fail the prognosis is bad. The failure of the heart is noticeable here long before it can be noted in the pulse, or in the sounds of the heart as heard at the apex.

Dr. Conner, in closing the discussion, said in answer to a question as to the method employed by Dr. Creighton in determining the intensity of the heart sound, that she first applied layers of filtered paper in a series of cases until the heart sounds were obscured. She followed this method until she had been able to convince herself that she could without this aid determine with sufficient accuracy for statistical purposes, the relative intensity of aortic and pulmonary second sounds.

Pericardotomy.—Dr. Morris Manges reported a case in which after the aspiration of 18 ounces of pus from the pericardial sac some forty ounces more had been removed by open incision under local anesthesia with eucaine. The operation was performed by Dr. Howard Lilienthal. Recovery had been complete and in six weeks the patient was able to leave the hospital. As the result of the operation Dr. Manges demonstrated that the patient had an adhesion of the pericardium and the heart with the scar tissues above so that at each systole there was a retraction of the overlying tissues. In addition to this there was the pulsus paradoxus, that is, a cessation of the pulse when the patient took a long breath. This pointed to the fact that adhesions of the pleura and pericardium existed which when the pleuræ were fully distended interfered somewhat with the heart's action. In this case there had been a tri-lobar pneumonia prior to development of the purulent pericarditis, the pus of which contained a pure culture of the pneumococcus. Two lobes of the right lung and the lower lobe of the left lung were affected. The prognosis in cases of bilateral pneumonia is usually considered very serious. Statistics seem to show that the prognosis is not as unfavorable as has been thought. During the last ten years at Mt. Sinai Hospital, New York, there have been 58 cases of bilateral pneumonia. Of these only 15 (26 per cent.) proved fatal.

Pericarditis in Pneumonia.—In 500 cases of pneumonia under treatment at Mt. Sinai Hospital, pericarditis developed as a complication in 11 cases. Of these 11 cases 5 died, a mortality of 45 per cent. It seems clear that all of the cases of pericarditis which develop during pneumonia were due to the pneumococcus. It is probable, also, that most of the cases of so-called spontaneous paricarditis are really due to an invasion of this same micro-organism which in some manner finds its way from the pulmonary passages into the pericardial sac, where the conditions are very favorable for its virulent growth. Under these circumstances, as on the meninges, it is always a pus-producing micro-organism. Pyopericarditis occurs especially as a complication of acute rheumatism, of pyemia and of osteomyelitis. One case of purulent pericarditis following a stab wound has been reported in which the only micro-organism that could be demonstrated in the pus was the colon bacillus. It is probable that pericarditis during pneumonia is often overlooked. The conditions around the heart, when the left lung is affected, are such as to obscure the most important sign of pericarditis, *viz.*, the increase of heart dulness. The to-and-fro murmur of the pericardial friction may last but a few hours and so never be present when a physical examination is being made.

Operation for Purulent Pericarditis.—Just as soon as it is established that pus is present pericardotomy should be done. All the reported cases in which aspiration alone was deemed sufficient for the removal of a purulent exudate have terminated fatally. Out of 35 cases of pyopericarditis operated on by Roberts, only 20 died. Of these 10 were in a distinctly septic condition before the operation was done, so that only 10 less than 30 per cent. died after operation. It is surprising how much pus may be removed from a pericardial sac. Fifty ounces, as in this case, seems a large amount, but the reports of other cases have shown even greater quantities. Eight pounds was removed in one case, a gallon in another, sixty-six ounces in still another, while ten liters was removed in a case recently reported in France. Notwithstanding such large quantities of pus the patients have a reasonable show for their lives if the open operation is fearlessly done.

Seventy Ounces of Pus from Pericardium.—Dr. Lewis A. Conner reported a case in which pericarditis developed after a severe pneumonia, and aspiration showed the presence of a purulent effusion. Thirty ounces of the fluid were removed by aspiration, and as the symptoms did not improve, the patient being in an extremely bad condition, Dr. Stimson operated under local anesthesia and removed nearly 40 ounces more. The patient's condition at once improved and the

alarming acute symptoms disappeared. The right pleura extended beyond the sternum, owing doubtless to the compensatory hypertrophy of the right lung, because of the pneumonia in the left. Despite the most careful precautions the pleura was slightly incised. It was at once carefully closed, but probably became infected, and the patient died of a purulent pneumonia a few days later.

Dr. Alfred Meyer asked if there was not some question in these cases of very large purulent collections, of an abscess in the connective tissue between the lobes of the lungs. There is ample room in this location for a large quantity of pus, and these metapneumonias are more common than is usually supposed. Their interference with heart action may lead to the diagnosis of pericarditis and the dislocation of the heart may cause the surgeon to incise them under the impression that he is incising the pericardial sac.

Premature Burial.—Dr. H. L. Garrigues read a paper on this subject which will appear in a later number of the Medical News.

M. Emile Camis of Paris then demonstrated his patented apparatus for the prevention of premature burial. Its important features are these: In the coffin-lid a valvular opening is made. Through this an iron rod with a ball on its end is passed, the ball being placed at about half an inch or less above the body of the person in the coffin. The other end of the rod is connected by a spring with a bell and a signal ball. The whole apparatus is enclosed and is thoroughly air-tight, and once it is closed it can only be worked from the coffin. A slight touch on the ball within the coffin is sufficient to ring the alarm bell for half an hour and to throw the brass signal ball up into the air, where it can be seen from a distance. At the same time, air and light are admitted into the coffin. If a supposedly dead person should revive, these arrangements would be sufficient to protect him from suffocation, the light would reassure him, and the alarm and signal ball would bring him immediate assistance. At the end of three weeks, or less if deemed advisable, the apparatus may be lifted out of the grave, the valve in the coffin-lid closes automatically, and the hole in the grave filled. The whole apparatus may be sterilized. It costs from $15 to $20, and may be used a number of times. While in use it is hermetically sealed.

NEW YORK ACADEMY OF MEDICINE—SECTION ON PEDIATRICS.

Stated Meeting, Held December 14, 1899.

Henry Koplik, M.D., Chairman.

Ichthyosis and the Thyroid.—Dr. Grieg presented a child, born of Bohemian parents, which had recently been under treatment for this disease in Mount Sinai Hospital. As in all such cases, the condition is worse in cold weather. The child presents noticeable anomalies in addition to the parchment-like induration of the skin. There is slight deformity of the mouth and ears and the peripheral circulation is interfered with so that the child's extremities are always cold. The thyroid gland can scarcely be felt.

In the discussion of the case, Dr. Jacobi said that the skin not being horny and being freely movable over the scant subcutaneous tissue, it was evidently a mild case of ichthyosis. In all probability the condition had originally been one of inflammation with destruction of the elastic fibers and of exaggeration of the normally copious secretions of sebum during the second half of intra-uterine life. Sebum thickened by epidermal cells and foreign material causes the scales and occasional warts and fissures seen in these cases. A few have been studied in connection with the thyroid in some instances and the extract of that gland has been tried as a remedy. In this case the thyroid is distinctly smaller than normal—so much so that the tracheal rings can be felt all the way down to the sternum, but a persistent thymus also seems to be present. When the child sits up straight there is a slight dulness of the percussion note over the upper part of the sterum. When the child is made to lean forward and percussion is continued the dulness becomes much more marked and extends to each side of the sternum. Although the child is eleven years old there seems no doubt but that the thymus gland still persists.

Persistent Thymus and Its Significance.—Dr. Jacobi said that during the last two or three years his attention had been called much more often than usual to the question of the possibility of diagnosticating a persistent thymus during life. Some years ago he saw a child who was suffocating. The case terminated fatally before anything could be done for it. The thymus was apparently not enlarged. At autopsy it was found to be very large. The case was probably one of those in which a sudden enlargement of the hypertrophied thymus causes a fatal issue. In many cases a persistent thymus may be diagnosticated if the child leans over while percussion is made. With reference to the etiological connection between this enlarged thymus and the ichthyosis nothing can be said with any assurance. It is possible that there is merely a coincidence in the two anomalies, ichthyosis on one hand and small thyroid with large thymus on the other.

Thymus Medication.—In a case of pseudohypertrophic muscular dystrophy extract of thymus gland was administered, at first in one-grain doses, then in two, three, four, and five respectively. Absolutely no effect was produced. There was no tachycardia, no flushing, no restlessness, no change in appetite or in the general condition. Then ten and then fifteen grains were given three times a day, also without producing any effect. Then, lest there should have been any deterioration in the preparation, fresh thyroid was ordered direct from the manufacturer and used in thirty and forty grain doses, but absolutely with-

out effect. Thymus medication was then abandoned.

With regard to the treatment of ichthyosis, it should be noted that there is always a thickening of the epidermis in these cases which can be gotten rid of to a great extent by a continuous bath. If the child be kept in a warm bath, with or without spirits of soap, for half a day or longer, the skin tissues will become pliant and soft once more and resume a healthy appearance. This treatment should be repeated several times. There is an absence of oil in the cutaneous tissues in ichthyosis and this is best replaced by lanolin inunctions.

Acute Intussusception.—Dr. Fred Kammerer considers that intussusception is nearly always a surgical disease and that its mortality can be best reduced by a recognition of this fact. As to the use of injections of water in order to reduce the intussusception, the greatest care must be taken not to use too great pressure. With a pressure of five feet of water cracks have been produced in the serous coat of a perfectly healthy intestine. It must be remembered in a case intussusception that the intestine is not healthy. There are a number of cases in the literature in which rupture of the intestine has been produced by too great pressure during injection which had been undertaken to reduce the intussusception. There are certainly a number of other cases which have not been reported. The use of injections should be discouraged after the first twenty-four hours because, as a rule, changes have taken place in the bowel during this time which would almost inevitably lead to infection of the peritoneum, even if the intussusception were overcome. As to the quantity of water that may be used in injection no definite rule can be given as the size of the intestine varies so much in different cases. It is certain that the hydrostatic pressure should not be allowed to exceed that produced by a height of three or four feet. Barker, in fifteen cases on which he operated, had tried preliminary reduction of the intussusception by water pressure eight times. In six his efforts seemed at first successful, but they proved not to be when the parts were examined after laparotomy. When the water injection is tried it should be done as soon as possible after the diagnosis is made and after complete anesthesia. The water should be warm. After a fair, unsuccessful, trial laparotomy should be performed at once. If this were done in all cases the mortality after operation would be very much reduced. As it is the delay after diagnosis and after the failure of injections leads to serious depression of the patient and makes the result of operation much more doubtful.

Operative Technic.—It is better not to exert any traction or just as little as possible in the reduction of the intussusception. Pressure exerted just above the apex of the intussusception forces it out very effectively. As a rule, after reduction, it is not necessary to do anything to prevent recurrence. Recurrences are not frequent after laparotomy. Their frequency under other forms of treatment is really due to the fact that reduction is never complete and so relapse is easy. When the intussusception is irreducible a total or partial resection is indicated. The mortality in complete resection has been very unsatisfactory. It is only recently that Kocher has reported success in five cases of complete resection and Eiselsberg in four cases of the same kind. Despite the prevalent notion that children do not stand major operations well, the result of operative treatment for intussusception shows the contrary. Barker, who has had a very large experience in this matter, says they stand these operations better than adults. As a rule it is easy to control hemorrhage and the shock is not so great as in adults.

Mortality of Acute Intussusception.—Dr. Gibson presented a table containing a report of 187 cases of acute intussusception that had been under treatment during the last ten years. Statistics were limited to ten years because the present technic has prevailed during this time. The total mortality was 51 per cent. The noteworthy feature was that even on the first day the intussusception in some was found to be irreducible. The indication therefore was to operate early. The longer the delay the greater was the increase of mortality and of irreducibility. Complete resection for irreducible cases gave an extremely unfavorable prognosis. Eiselsberg's cases, which have been quoted, were really not cases of acute but of chronic intussusception. As to Kocher's cases it is not clear that they were done for acute conditions.

Dr. Frederick Holme Wiggin said that some years ago he assisted Dr. J. Lewis Smith in the treatment of some cases of intussusception by injection. There seemed no doubt in his mind then that it would have been less trying to the patient to have done a laparotomy. Farther study of the question has shown him that while the injection is much more dangerous it is much less effective. The success of the injection is always problematical and seeming cure may prove eminently fallacious and precious time is lost. It seems evident now that laparotomy should be done as soon as the diagnosis of intussusception is made. Children stand laparotomy well and the operation can be done in fifteen minutes or even less.

Early Laparotomy.—Dr. Willy Meyer said that early abdominal section is the proper indication. If it were known with certainty what could be accomplished by injections and if delay were not dangerous, the question of injection might be seriously considered. Ileocecal intussusception is the most frequent form of the affection, and this, it is generally conceded, is not affected by injections at all. In a recent case of operation for intussusception, Dr. Meyer failed to assure himself that the bladder was empty before making the abdominal incision. The organ proved to be full of urine and extended up to the umbilicus and absolutely precluded the possibility of getting at the affected intestine. The operation

had to be delayed on this account. This is a complication that it is well to remember.

In many cases of chronic intussusception it will be found that malignant disease of the intestine caused the paralysis of peristalsis which resulted in the intussusception. In a recent case in which operation was performed with apparent success, the patient did not regain health and strength. He was sent to the country and returned much worse. Suspicion of malignant discase was aroused and the specimen which had been preserved was opened and proved to have a round-celled sarcoma for its nucleus. The patient died from recurrence.

Injection Methods.—Dr. Jacobi said that too much had been said about immediate operation. In our day superfluous operations go unpunished, thanks to clean hands, knives and wounds, and so it is easy to say, operate at once! Not a few unnecessary operations have been done for intussusception. There is no doubt that many cases can be cured by injection. For this purpose the water should never be more than from twelve to eighteen inches above the patient. Six years ago in discussing this matter before a meeting of the Academy some one suggested that the pressure of fourteen feet of water should be employed. This was manifestly a serious mistake of a gentleman who applied the hydrostatic laws of iron pipes to the human gut. The patient's head should be down and the hips well up and complete anesthesia by chloroform should be obtained. Warm water should always be used. While the water is slowly flowing in the anus should be closed and the abdomen gently manipulated. Sometimes the first irrigation proves successful; then opium should be given to prevent peristalsis and a relapse which is quite frequent. If a single injection proves unsuccessful it should be repeated three or four times at a couple of hours interval. If at the end of a half a day there is no relief operation should be performed.

Dr. Kerley reported two cases in which he had succeeded in effecting a cure by injections, the source of the water not being more than two feet above the patient. Complete anesthesia is necessary for success and the abdomen should be gently manipulated. This procedure may be continued for thirty minutes and then, after an interval of a couple of hours, the anesthesia and manipulations may be repeated once. After this operation should be done.

Recurrence.—Dr. Koplik said that he had recently seen a case in which the reason for seeming recurrences in certain cases of intussusception was very well illustrated. In the morning the patient had had all the symptoms and these had been relieved by injection. At three in the afternoon there was a recurrence of the tumor and of the symptoms. Relief was once more afforded by injections. The rectal tube was then left in the hope that it would help to prevent recurrence by relieving the intestine of any gas that might be present. The symptoms, however, recurred and the patient died. At autopsy it was found that the caput coli and the ascending colon had been inverted into the transverse colon. These had been reduced, but the ileocecal intussusception, the commencement of the process and the important element in it, had not been affected by the injection. As a matter of fact these cases of ileocecal invagination cannot be cured by injection.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held December 18, 1899.

The President, Frederick Holme Wiggin, M. D., in the Chair:

Alcoholic Cirrhosis in a Baby.—Dr. R. Abraham presented a baby sixteen months of age in whom some six weeks ago marked ascites developed. On percussion and palpitation the liver seemed to be enlarged. The amount of fluid in the peritoneal cavity became so large that it interfered very seriously with the child's respiration. It was removed by tapping and then there was no doubt of the existence of an enlarged liver. The history of the child was carefully inquired into and it was found that from about six months of age it had been given beer very freely. There seems no doubt then that the affection of the liver is a hypertrophic cirrhosis due to alcohol.

Dr. Illoway said that in a certain number of cases liver affections develop in children to whom alcoholic stimulants in one form or another had been given rather freely. The affection of the liver seems to be dependent much more on beer than on other forms of alcoholic drinks. While it is by no means frequent it occurred often enough to make it a fit subject for warning to parents.

Cystitis.—Dr. Raymond Guiteras read a paper in which he discussed the present position of medical men with regard to this important subject. The three important symptoms are pain, frequency of urination, and pus in the urine. All three of the symptoms may not be present in every case, but where one of them is absent it is well to leave the diagnosis of cystitis an open question until a more careful study of the case has been made. An irritable bladder is often diagnosticated as cystitis, or the presence of irritating urine may lead to the suspicion of bladder trouble, when the real affection is in the kidneys. Acute cystitis is usually due to gonorrhea and develops in the third or fourth week of that disease, or after instrumentation for posterior urethritis. It must be borne in mind that an affection of the posterior urethra gives practically all the symptoms of cystitis. This may develop after horseback-riding or excessive bicycle riding, or as the result of exposure to cold.

Differential Diagnosis.—The various conditions around the neck of the bladder which simulate cystitis, namely posterior urethritis, prostatitis and seminal vesiculitis, can be diagnosticated with reasonable certainty. For this the three

glass test is the best. In posterior urethritis there will always be less pus in the third glass and most pus in the first glass in addition to some urethral shreds. In cystitis there is no fever. Guyon says that when fever is present there is always a complication and not a simple cystitis. In pathologic conditions of the prostrate there is pain in the rectum, especially during stool and at times even when sitting down. Rectal examination discloses enlargement of the prostate and very often thickening around it, with considerable tenderness. Seminal vesiculitis may also be detected by rectal examination and by thickening of the tissues in the neighborhood of the seminal vesicles. Chronic cystitis is always secondary. Germs that are present in the urine produce a pathologic condition of the bladder walls when predisposing causes are present. Any irritant that will cause hyperemia of the bladder walls is apt to produce this condition. Cantharides, alcohol, the hyperemia of excessive sexual indulgence, the irritation of a foreign body such as a calculus, or the presence of tubercle in the vesical tissues act in this manner.

Differentiation from Kidney Disease.—Chronic cystitis is often diagnosticated when really the pathologic condition present is in the kidney. The points of differentiation are: Almost constant presence of pain in the loin when the kidneys are affected, the tenderness on palpation in this region and the enlargement of the organ which can be felt on bimanual examination. Kidney affection when it leads to the secretion of irritating urine may cause frequent urination, but this symptom is more distinctive of bladder trouble and when it is accompanied by pain behind the pubis the affection is almost surely in the bladder. In pyelitis the urine is always acid. In cystitis the urine is always alkaline. In kidney trouble corpuscles are more degenerated than when the purulent process is in the bladder, and more epithelial cells are found to be present. When the affection is in the kidney casts of blood and pus and hyaline casts containing granular detritus are found. Bladder irritability may be diagnosticated from chronic cystitis. The cystoscope is important for the diagnosis of doubtful bladder conditions. In chronic cystitis it very clearly shows the presence of the thickened, gelatinous-looking bladder wall, with streamers of muco-pus here and there and occasional red patches of hyperemia, if the pathologic condition has existed for some time. In very chronic cases ulcers will be noted with whitish, elevated, gelatinous edges and the floor of the ulcer hyperemic, or covered here and there with pus. If tumor or stone is present it can be seen and the character of the tumor may be determined, whether malignant, benign, sessile or pedunculated.

Treatment of Acute Cystitis.—The most important point in the treatment of acute cystitis is rest. The next is hot sitz baths. These determine the blood to the surface and lessen the acuity of the process within. They should be taken twice a day. Great relief is often afforded by hot rectal injections. The urine should be made unirritating by alkaline diluents. The antiseptics, such as the benzoates and salicylates, often give great relief by changing the reaction of the urine and making the pathologic process less acute. The antispasmodics, belladonna and hyoscyamus, should be administered if needed, and where the local tenesmus is very great they should be given by suppository. Irrigation by the Janet method with permanganate of potash, beginning with a solution of 1-4000 and increasing the strength 1-1000, is often very effective. Solutions stronger than this should not be used. Where the permanganate is not effective, nitrate of silver should be used, beginning with a 1-16,000 solution and gradually increasing its strength.

Treatment of Chronic Cystitis.—Chronic cystitis may be benefited even when its cause cannot be removed. Antiseptics and antispasmodics do a great deal of good. Irrigations are often of the greatest service. While in an acute cystitis no instrument should be passed into the bladder, in chronic conditions this is not contraindicated. Where ammoniacal urine exists the use of urotropine, seven to ten grains three times a day, sometimes does away with the necessity for irrigation. There is nothing to equal it in its effect on the symptoms in these cases. Where stricture and enlarged prostate exist they must be treated directly. Slight strictures should be stretched; tighter strictures should be cut with an Otis or Maisonneuve urethrotome if they are in the anterior urethra; if in the deep urethra an external urethrotomy should be done. For slight strictures a soft rubber catheter should be used to draw the urine. If this does not pass, then a woven catheter should be employed. For enlarged prostate resection of the vas deferens and castration are not used at the present time. Very large and hard prostates, the door-knob variety, should be enucleated. The operation is easy as the fibrous tissue of the prostate can be easily shelled out of its capsule. Bottini's method should be used in small enlargements of the prostate where the middle lobe mainly produces the obstruction to urination. Enucleation is very difficult in these conditions. Tubercular cystitis should be treated locally, but general treatment should be simultaneously employed.

Cystitis in Women.—Dr. A. J. C. Skene of Brooklyn said that the treatment of cystitis in women does not differ from that of the same condition in men. Preventive treatment is, however, much more important in women than in men. The etiology is very different in the two sexes. In women cystitis is very often due to some form of infection from without. After parturition and surgical operations, when catheterization has been necessary, it frequently happens that cystitis develops. Formerly this was considered to be the result of the use of unclean instruments, but the most sedulous care in the cleansing of instruments will not do as much to prevent cystitis as the use of a soft catheter. Of

late years he has found that the use of a soft catheter is followed by much less cystitis. Saleswomen and those who stand for a long time are more liable to cystitis than are others. Movement on the feet does not seem to give much occasion for the development of the affection. Examination with the endoscope will sometimes show ecchymotic spots in these cases. They improve under irrigation and rest, but if the cystitis continues ulcers develop and the cases become very chronic. Vaginal cystotomy is not of much value unless treatment is carefully carried out at the same time. In many of these cases in which after thorough drainage of the bladder through the vagina for weeks the woman is allowed to get up, the scar tissue breaks down, ulceration sets in and the condition is no better, and may be worse than before. In the treatment of these conditions by irrigation borax has been found better than boracic acid. It must be remembered that the bladder refuses to distend rapidly; therefore the injection should be made slowly. It should be rather instillation than injection. In emptying the bladder it should not be allowed to contract down upon the end of the catheter or an injury to the mucous membrane will almost surely be produced. In using nitrate of silver the solution should not be stronger than one grain to the ounce. It is better to repeat the injection than to increase the strength of the solution. Ulceration will not be relieved by these mild applications. The endoscope should be used and applications should be made directly to the ulcerated patches. For this purpose nitrate of silver, half a dram to the ounce, or pure carbolic acid should be used, or the actual cautery may be employed if the operator is skillful in its use. Whatever method of cauterization is used it should be extremely local in its effect and should touch only the ulcerated portions.

Causes of Cystitis.—Dr. Fuller said that in women the shortness of the urethra frequently leads to infection. Normally the urethral flora is abundant and not infrequently finds its way into the bladder. Auto-infection does not, however, take place unless there is trauma. In general, the individual is a very important factor in both sexes. The germs may pass through a healthy kidney and remain for a time in the bladder without producing any serious symptoms, but if there is a pathologic condition of the bladder infection may take place. In addition to the cystitis ordinarily described there is a severe type of the affection which affects not only the mucous membrane, but also the muscular coats and the peritoneum, as well as certain structures in the neighborhood of the bladder. This pericystitis has been especially described by the Necker school in Paris. The bladder is often so bound down by adhesions that it is impossible to inject fluid into it even under ether. The prognosis of these cases is very bad for practically nothing can be done for them.

Technic of Injections.—Dr. W. K. Otis said there is distinct danger of mistaking kidney disease for bladder disease. Often in cases of tuberculosis or stone in the kidney, operations have been done on the bladder although absolutely no pathologic condition existed in that viscus. In irrigation the catheter should be introduced just beyond the external sphincter but not beyond the internal sphincter. If the catheter is pushed farther on into the bladder the injection fluid does not touch the neck of the bladder where it is most needed, but flows out again through the eye of the catheter. The best position for irrigation is the upright one. Thus the bladder can be washed out thoroughly. The double current catheters should not be used, for the fluid takes the shortest route out through the catheter and all parts of the bladder surface are not touched by the fluid.

Sterilization of Catheters.—Dr. Guiteras, in closing the discussion, said that the soft catheter is of course the best one to use, but it is often impossible to pass it. The woven catheter is much more satisfactory in this respect, but the difficulty thus far has been to make it sterile. Recent experiments at the Post-Graduate Medical School and Hospital show that the Schering and Glatz sterilizer producing formaldehyde gas kills the germs on a woven catheter without injuring the instrument.

Syphilis of the Nervous System.—Dr. W. Leszynsky then read a paper on this subject. He said that in every nervous case it is important to look for syphilis in the history. It must also be borne in mind that nervous disease may exist in a syphilitic patient without its necessarily being syphilitic in origin. There is an old tradition that syphilitic nervous disease has a favorable prognosis. Although such a prognosis is more favorable than that for other nervous diseases, it is unjustifiable to think that syphilitic nervous disease practically always gets better. Syphilis itself is incurable and yet most amenable to treatment. This looks like a paradox, but is eminently true. Early treatment is extremely effective and sometimes prevents the appearance of tertiary symptoms. Cases of syphilis are sometimes so mild however, that they are overlooked and it is especially in these that after-effects are noticed in the nervous system. Where nervous disease is evidently syphilitic in origin mercury and the iodides should be given for two to three months. In exudative conditions such treatment is of value, whereas in degenerative conditions harmful results may follow. Tabes and general paralysis while due to syphilis in certain cases, are practically never helped by mercury and the iodides. Certain symptoms of these diseases are even made worse by these drugs. Optic atrophy certainly progresses more rapidly under the use of mercury.

ORIGINAL ARTICLES.

PRURITUS ANI.[1]

BY J. P. TUTTLE, M.D.,
OF NEW YORK;
PROFESSOR OF RECTAL SURGERY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

THE term pruritus ani has for the scientific physician only a vague significance, but for its victims it is portentious with evil. To the former it means an indefinite symptom referable to divers and sundry pathological causes, sometimes to none, but to the patient it means an agony besides which pain would be pleasure.

The disease is marked by itching of greater or less degree about the anus. Its severity is governed largely by the nervous condition of the patient. I do not mean by this that it is worse in hyperesthetic individuals, but on the contrary it is generally so in cases of dysesthesia or hypopselaphesia, patients who bear pain well and whose sensations of touch are below normal. Some are only annoyed slightly after exercise or overheating and are relieved by almost any application to the parts; in others the itching is so acute and exacting that they must scratch under whatever circumstances and thus they are debarred from society lest their infirmity cause offense. Some patients never suffer in the day-time but as soon as they are in bed and just about to fall asleep the attacks come on and continue until morning. These are the most distressing cases and the most severe. With them it is more than an itching; it is a stinging, burning, aggravating pain which scratching does not relieve, and to which applications of water, hot enough to blister, are absolutely pleasant. It seems just within the anus but when the patient introduces the finger or pile pipe to relieve it, the sensation always recedes to just above the point of touch. Sleep is impossible until the patient, worn and exhausted from the vigil, dozes off about dawn and awakes after a few hours rested somewhat but not refreshed. They get through the day fairly comfortably so far as the itching is concerned but dreading the return of night and its inevitable suffering. The wan and exhausted look upon the faces of chronic sufferers from pruritus resembles much that of the morphine habitué who has been deprived of his only solace and the desperate frame of mind which develops is alarming to the friends and physician. I have never known a case of suicide from this cause but having heard it threatened so often I can not but believe that some men have taken their lives rather than continue in their torture. The disease is generally more or less chronic when the rectal specialist sees it, as it begins insidiously; the suffering is not great at first and careful examination of the parts by touch and the mirror reveals nothing abnormal to the patient. He takes it as a sort of joke at first and speaks lightly and in contempt of it. It reminded one of his first night on our great western prairies. When the camp fires had died down and he had just dropped to sleep the noise of a thousand howling wolves began. He awoke with horror and lay all night with gun in hand expecting surely to be devoured, but determined to sell his life as dearly as possible. But when the morning came all that he could see of this ravening pack was one poor lone coyote perched upon his earth hill and grinning from ear to ear. He expected after such a night of torture to find his anus in a terrible condition and was provoked to think he could suffer so much and have nothing to show for it.

Sudden changes of temperature, especially from cold to heat, aggravate the itching, as may also a change of climate as from inland to seashore. I have one patient who claims that he is always worse when near salt water. This statement must be taken *cum grano salis*, however, as his diet and habits are different there and at home. The itching may be subdued for quite a time and relighted by some article of diet or drink. Each case presents a problem in itself as to idiosyncrasies. The physical symptoms are very slight in the early stages of the disease, but after it has existed for a period they become more or less marked according to the etiological cause. I am not a believer in *pruritus ani essentialis*. The constitutional condition upon which the theory of this disease is founded I admit, and reckon it an important element; but I insist that there is always an exciting cause for the disturbance, and upon this cause will depend the physical appearance of the parts. If we discuss pruritus ani as a disease *per se* we must go into a description of all the various conditions which produce itching of the anus, such, for example, as eczema, moist, dry and marginatum, herpes, pediculi, erythema, fissure, prolapsus recti, hemorrhoids, urethral stricture, etc., etc. On the other hand, if we consider it simply a symptom or complication of these affections, as it really is, then it should be treated of under those diseases and our subject will have been annihilated, unless we evolve from our imagination a pruritus ani essentialis—a disease without a pathology, an effect without a cause. We are thus between the horns of a dilemma and it is somewhat difficult to extricate ourselves. It is the purpose of this paper to discuss those so-called cases of essential pruritus

[1] Read before the American Proctologic Society, Columbus, O., June, 1899.

and evolve a little structure from the chaotic opinions concerning it. Those who speak of it as such, or as neuralgia, or as an affection, reflex or direct, of the lower end of the spinal cord, are logically led to the description of the physical condition of the parts as a result of the disease itself. They speak of the excoriation, the moist secretion, the dry scaly appearance, the hypertrophied mucous folds, the fissured mucocutaneous border and the depigmentation of the parts as the results of pruritus ani. It is true that the pruritus exists before these conditions are observable to the naked eye, but it is equally true that the itching is never very severe until one of these pathological conditions has developed. Such pathological changes may be well within the margin of the anus and hidden from the careless observer, but some morbid condition is always there when the pruritus is marked. The diseases which cause these physical changes in the parts we know full well, and these diseases occurring in the dysesthesic or hypopselaphesic patient, instead of causing pain, produce itching until the scratching and irritation of the parts develop actual pain. I propose to discuss these diseases and their influence in the production of pruritus in this paper and this leads us to the etiology of the disease.

Etiology.—I can but enumerate the many causes of pruritus ani as laid down by different authors. A discussion of them would involve the whole subject of rectal diseases. As an etiological factor many of them are problematical, but as most of them are patent to the most casual observer they should always be removed if possible in the course of treatment for pruritus. They are: Oxyuris vermicularis, constipation, impacted feces, hemorrhoids, fissure in ano, fistula in ano, ulceration of rectum or anus, neoplasms of the rectum, pediculi, parasites, erythema, eczema of various kinds, diseases of the crypts, herpes, stricture of the urethra, stone in the bladder, foreign bodies in the rectum, pregnancy, leucorrhea, gonorrhea, hepatitis, nephritis, neuralgia, diseases of the spinal cord and brain, rheumatism, uricemia, catarrhal diseases of the rectum, sigmoiditis, and colitis.

I have so frequently seen piles removed, fistulæ and fissures cured, pregnancy terminated, hepatic diseases get well, etc., and yet the pruritus remain that I have grown skeptical of most of them as etiological factors. In the last five causes, however, together with parasites and oxyurides, I have developed the most profound faith. As to the oxyurides little need be said at the present time. Their influence, the symptoms which they produce, and the methods of determining their presence are too familiar to be repeated.

Parasitic diseases are of more importance and require careful macroscopic and microscopic observation to determine their presence. Those which may give rise to pruritus are erythrasma, the various tinea, scabies and pediculi. It requires somewhat of a dermatological training to be able to diagnosticate and properly treat these diseases, and to those not trained in this branch of medicine the services of a specialist are of the utmost importance in doubtful and obstinate cases. When this form of disease exists we may run the whole gamut of parasiticides before we relieve our patients unless an accurate diagnosis is made at first. I must refer my readers to special works on dermatology for the study of this part of our subject, but I would urge a constant appreciation of the fact that these little animal and vegetable growths may be the exciting causes of the most intractable and severe pruritus. Moreover it must be borne in mind that the irritation produced by their presence and the consequent scratching may produce pathological changes in the parts identical with those produced by other diseases and thus a complication will arise demanding a combined therapeutic management.

Rheumatism and uricemia, if not identical, are intimately associated in the human economy. Gastro-intestinal, particularly colonic, fermentation is a most important element in both. It is often difficult to distinguish between rheumatic and lithic acid diatheses. Happily the same treatment is effectual in both. For some years past I have believed that these two conditions are potent causes in the production of pruritus ani, and the more I see and observe cases the more am I convinced of the constitutional element in their production. A large majority of my pruritus patients have suffered more or less from rheumatism or uricemic symptoms. The urine of these patients is generally loaded with uric acid or its derivatives and their distress is almost invariably in direct proportion to this condition. Errors or excesses in diet which produce increase of uric acid or intestinal fermentation are more than likely to bring on exaggerated attacks of pruritus, and when the constitutional derangement has been relieved the pruritus just as promptly subsides. I recall one case in which the indulgence in sweet wines, pastry, or excess of carbohydrate foods would bring on congestion, redness and itching about the anus in a few hours, and if the condition was not soon remedied this irritation, swelling and redness would spread like a prairie fire to the buttocks, scrotum, abdomen, and even to the face. But with all its dissemination the pruritus was the one constant and unbearable symptom. I could relate many similar cases, although perhaps less severe, but in all of them the same constitutional element existed and under proper treatment they recovered, whereas all the local applications in creation would have given temporary relief alone. Do not understand me to belittle local applications. They are our sheet anchors of success in that they relieve our patients' suffering while we treat the disease, but they are too often vaunted as specifics and alone depended on in the treatment of pruritus ani. The constitutional element in producing pruritus is an important fact and the more we recognize it the greater will be our success in treatment.

Catarrhal diseases of the anus, rectum, sigmoid and colon are the processes referred to when I said above that we knew the causes of the pathological changes about the anus in pruritus ani. We

may discuss them together in relation to pruritus, although membranous colitis and sigmoiditis are distinct in their symptomatology. There are practically three kinds of this disease; the acute, the atrophic and the hypertrophic catarrh. The two latter may result from the first but, in general, patients with the chronic forms give a very indistinct history of having had the acute variety. I have discussed these diseases elsewhere in print and shall only here recall the physical changes which they produce and compare them with those found in pruritus ani. Before doing this, however, let me say that those who claim the severe and chronic types of pruritus ani to be without physical or pathological changes have certainly seen very few cases or have observed them superficially. All the chronic cases I have seen have presented very marked changes about the anus and this statement agrees with the opinion of Allingham and other noted specialists.

In the acute catarrh of the rectum there is very little manifestation of disease about the anus, until the secretive or suppurative stage begins. If this continues for a time the skin and mucocutaneous surfaces become moist, sodden, sometimes excoriated and inflamed, taking on the nature of a superficial cellulitis. The disease does not often assume such a serious phase and when it does pruritus is not so marked as actual pain. In the milder form heat, heaviness, aching in the sacrum and mild itching in the anus are its symptoms.

In the hypertrophic catarrh and membranous colitis the pathological condition with which we have to deal is hypertrophy of the mucous membrane and Lieberkuhn's follicles, attended with hypersecretion, exfoliation of the epithelium and septic infection. Perhaps the infection might be placed first. Pruritus is a symptom early in this disease and becomes more and more marked as the disease process approaches the sensitive margin of the anus and as the acrid secretions flow over, irritate and infect the parts. The appearance of the skin about the anus in the chronic state of this disease is moist, white, sodden, like a washerwoman's hands. The mucous membrane is swollen and edematous, the rugæ are more marked and the mucous folds hypertrophied. After some time the irritation, scratching and chafing of the parts develops an erythema, excoriation, or even ulceration. Together with these changes and the exfoliation of the epithelium of the skin comes the depigmentation of the parts, an appearance on which Allingham lays so much stress in pruritus. These are the changes in a greater or less degree which we find in many of our most annoying cases of pruritus and the reason they do not recover is that we treat them from below instead of from above where the root of the evil is.

The atrophic catarrh is exactly the opposite of the above. The glands are atrophied, the secretions deficient, the surfaces hot and dry and without normal lubrication. In consequence the stools are constipated, hard and lumpy, and the sphincter is generally contracted. The disease extends to the mucocutaneous border and this area becomes so dry and brittle that any distention of the parts by the feces or pulling apart of the buttocks causes numerous little cracks or fissures which are irritated by the touch of clothing or passing feces and thus set up the most intolerable itching. I have frequently produced these little cracks and set up the pruritus when showing the condition to my classes. These little fissures often run or begin well up above the anal margin and may develop into true fissures. They are easily overlooked and I truly believe that these are the nerve-wrecking cases in which so many observers say there is no pathological change or cause. There may be no change on the outside but just within the anus or even higher up the cause is almost surely to be found. These pathological changes are the ones which I have found most often in obstinate and obscure cases sent to me, and they tally remarkably with descriptions of pruritus ani by our best authors.

Aside from cases due to the specific causes mentioned above I believe all the cases of severe pruritus ani may be traced to one or the other of these conditions of rheumatic, uricemic, or catarrhal disease, and furthermore the proof of it lies in the fact that patients get well when treated in accordance with this pathogeny. But one will ask why, then, is it so much worse at night? I answer, for many reasons. Patients generally go to stool, bathe, rub, or scratch themselves before going to bed; heat or change of temperature always makes superficial irritation worse; the recumbent position brings the parts closer together; and the influence of night and quiet on the mind, making all the senses more acute, serves to make the patient more sensitive to the irritation.

Treatment.—For the scientific physician all treatment must be based upon his conception of the pathology of the case. To those who have followed me in this discussion I need say very little on this part of the subject. Remove the pathological or reflex cause, treat the disease and not the symptom. Pruritus ani is only a symptom. If operations are necessary to remove what you believe to be the cause, do them, but be careful in your prognoses as to permanent relief. Fissure, fistula, hemorrhoids, condylomata, may all be due to the same disease which causes the pruritus and they may be removed and yet the pruritus remain. As to the rheumatic and uricemic cases the text-books upon general medicine are safe guides in treatment. Nitrogenous diet, alkaline diuretics, salicylic compounds and hot baths compose the general routine of my treatment. The management of catarrhal diseases I have described in *Mathews Medical Quarterly*, 1894, and in the *New York Medical Journal*, 1898. I wish here to express my increasing faith in the use of the modified Kelly tubes, the long Wales bougies, the aqueous fluid extract of krameria and the strong solutions of argonine.

In the local treatment we have our means of relief while radical cure is being attained. Judgment and experience alone can guide us in the selection of a remedy. If our patients would bear

with us long enough we would all find a remedy to relieve them by trying one after another of those recommended in the text-books. But it taxes our ingenuity to apply the right one at first. Some need stimulation, some need soothing. Hot water is generally acceptable, but sometimes cold is more so. Carbolic solutions, larkspur, black-wash, salicylic acid, chloral hydrate, chloride of chalk, extract of conium, extract of strammonium, camphor, cocoaine, tar, etc., etc., may all be of use in one form or another. I have learned largely to rely on a combination of carbolic acid, ten to twenty per cent., salicylic acid, two to ten per cent., boric acid, five per cent., glycerine or cold cream, ad. one hundred per cent. I have used ichthyol with great benefit and when there is pain at stool, conium and cocaine have rendered me much service. Since I have treated pruritus on the pathological theory detailed above for the past five or six years, I have not failed of complete and more or less permanent relief in any case. I have not found it necessary to curette the parts, apply the actual cautery, or still less to resort to the radical operation of dissecting away the parts that itch. I would say the diseased area but this would involve too much according to my theory. Having determined the type and variety of the disease producing pruritus, it is not difficult to manage, and in most cases we may confidently expect a radical cure.

THE GREAT DRAINAGE CANAL AT CHICAGO.

BY J. A. STEWART,
OF BOSTON.

PUBLIC attention has been called to the colossal enterprise in which Chicago has been engaged for the disposal of its sewage by the fact that the great construction is now completed. The water was permitted to flow through the sluice-gates of the great controlling works at Lockport, Ill., on January 17, and the canal was thus formally and officially opened.

The character and importance of this great sanitary enterprise are not fully apprehended. It is not a canal with locks to regulate the flow of water, but an open channel 160 feet wide at the bottom and 38 feet deep. The construction was begun in 1892. It has cost about $33,000,000 to date. Its purpose is to unite the south branch of the Chicago river to the Desplaines at Lockport, Ill., whence it will flow to the Mississippi river. All the sewage now emptying into Lake Michigan is to be intercepted. It will then be turned into the Chicago river. With it will pass a volume of 20,000 cubic feet of water from the lake. This will assist in producing a current. It will also dilute the sewage.

When first opened the canal is to discharge 10,000 cubic feet of water per second, which is about 5 per cent. of the amount now flowing through the Niagara river. The quantity of water to be discharged is to be fixed by the state legislature. This is done with a view to protecting the valley of the Illinois from contamination. When the population of Chicago shall exceed three millions, the quantity of the discharge is to be increased proportionately. The amount of the original outflow is very great. The engineers estimate that it will raise the low-water mark of the Mississippi one foot at St. Louis.

The contention on which some of the opposition which has arisen has been based, is that the Chicago river is inadequate to furnish the required amount of water with the velocity of current fixed by the Drainage Board. The objection is naturally not supported by the bold engineers of the undertaking. The achievement of such an immense enterprise, it is claimed, is made entirely feasible by the peculiar geography of the great lakes. While Michigan and Huron are practically on the same plane—about 580 feet above the sea—Lake Erie is only about 8 feet lower, and Lake Superior poses as an independent basin 20 feet above its sister-lakes. It is asserted by a high scientific authority that the basin of the lower three of the lakes is so delicately poised that only four feet of rock and two of gravel at Chicago prevent them from spilling over into the Mississippi Valley at high water. The rock bottom of the Niagara where it leaves Lake Erie is only 30 feet lower than the rock shelf which forms the barrier west of Chicago. It seems that there is an old glacial outlet into the Mississippi Valley, into which the drainage canal will now turn a portion of the water of the great lakes southward. The Chicago engineers appear, then, simply to be carrying out at great expense of time and labor an unutilized topographical plan. Nature herself seems to have had such an outlet in mind.

The peculiarly bold aspect of the scheme is seen in the fact that the promoters did not deem it necessary or even advisable to get the consent to their project of other parties whose interests might be affected by it. The whole enterprise has consequently been a radiantly litigious one from the beginning.

The channel's depth, as has been stated, is 38 feet. This gives a capacity for a depth of water of from 25 to 35 feet. The current will have a speed of one and one-fifth miles per hour. Either 300,000 or 600,000 cubic feet of water can be carried through it per minute. Experts have declared that this will permanently lower the level of the three lower lakes from 3 to 8 inches and cause a corresponding reduction of from 240 to 700 tons in the carrying capacity for the large vessels of the lakes. The question of the lowering of the lake level is undoubtedly an important one. A feasible remedy has been proposed, however. It involves the storing of water in Lake Superior and letting it down when needed. The present shallowness of all the Lake Erie harbors has made necessary the work of deepening the navigable channel two feet by the government in recent years, at a cost of two million dollars.

The inland cities south of Chicago, too, are naturally concerned as to the effect of the Chi-

cago discharge on the Illinois river. The question of overflow has become an interesting one to dwellers along the river-banks.

Four results have been tabulated as the ends to be gained from the opening of the canal, *viz.*, (1) Protection of Chicago's water-supply from pollution; (2) purification of the Chicago river and its branches; (3) discharge of flood-waters without overflow; (4) disposal of all the sewage of Chicago without detriment to other communities. The first three points are conceded to have been achieved: but the fourth one has been of vital interest to the people of St. Louis. This is not surprising, since the discharge of the sewage of Chicago by the canal means a delivery into the Mississippi, from whence St. Louis draws its water-supply, at a point only forty-five miles above the city. This opposition culminated in a report by an investigating committee, which implied that Chicago is bound to purify the sewage before casting it upon the waters to contaminate the water-supply of a neighboring city. The report went so far as to urge that by the general laws of the United States, the pollution of interstate streams must be stopped, and that state and municipal regulations will demand the purification of public water-supplies under suspicion. A purification plant in connection with the Chicago works would cost about fifty million dollars, and three million dollars each year for maintenance; to construct which, it is pointed out, is asking a good deal even of Chicago. In view of the present condition of St Louis' drinking water, which is a murky and opaque beverage trustingly imbibed by the masses, it might seem pertinent on the part of Chicago to make the counter suggestion that, in its own interests as well as that of a neighboring city, St. Louis should install a filtration plant.

The fact that any gigantic cesspool, such as the Chicago river virtually constituted, is a menace not only to the health of the immediate community but also, by the laws of infection, its dangers are constantly being scattered far and wide, ought to facilitate any attempt to abolish it. Very little would be left of Chicago sewage by the time it reached St. Louis. The processes of dilution and evaporation have a distance of three hundred miles in which to perform their beneficent work. The scheme of the drainage canal, it is to be kept in mind, has a wider importance and significance than a purely local sanitary expedient. In its broadest conception, it assumes the dignity and power of a wide commercial enterprise in furnishing a navigable waterway which will not only satisfactorily dispose of all the water and waste of Chicago and all the cities along its banks, but also permit vessels to come down through it from Lake Michigan to the Gulf of Mexico. The Chicago engineers have foreseen the feasibility of diverting 15 or 20 per cent. of the water of the great lakes into the Illinois river, with locks to carry ships past the rapids that would be created. The legislature of Illinois, it seems, four years ago declared in favor of the construction of a trunk waterway through the State of such dimensions and capacity as to form a homogeneous part of a through route from the Atlantic seaboard to the Gulf of Mexico. The whole enterprise, it is seen, is surpassing in boldness. The drainage canal thus becomes the chief factor in a scheme for the improvement of internal navigation practically without precedent.

This is a plan not without interest to the people generally. And it is pleasant to think that while New York, Philadelphia and Boston have to pay enormous sums for pure water, Chicago is to have an abundant supply by simply pumping it through the mains from the big blue lake at its door.

EXPERIMENTAL RESEARCHES ON THE EFFECTS OF INCREASED BAROMETRIC PRESSURE AND OF FOREIGN BODIES IN THE PHARYNX, ESOPHAGUS, TRACHEA AND LARYNX.

By GEORGE W. CRILE, A.M., M.D.,
OF CLEVELAND, OHIO;
PROFESSOR OF CLINICAL SURGERY AND APPLIED ANATOMY, CLEVELAND COLLEGE OF PHYSICIANS AND SURGEONS; SURGEON TO ST. ALEXIS AND CLEVELAND GENERAL HOSPITALS

I. Effects of Increased Barometric Pressure.

Methods of Research.—The animals were all reduced to full surgical anesthesia by ether before the experiments were begun and were killed before recovery from it. Respiratory tracings were obtained by means of a rubber tambour, attached to a canvas band, encircling three-fourths of the circumference of the animal's chest. This energized a writing-style attached to an organ-key mechanism. Respiratory tracings were obtained very accurately. Blood pressure was recorded by means of a mercury manometer. The drums were revolved by a mechanism so made as to be capable of a variety of movements, ranging from one revolution in thirty minutes to eighteen revolutions per minute, so that any phase of any given tracing might be duly recorded. The following is a part of a rather extended research which enable us to estimate the reliable reduction with comparatively few experiments.

Preliminary Remarks.—On entering an atmosphere of increased barometric pressure most persons experience some peculiar symptoms, such as oppression, dizziness, occasional fainting, difficult breathing, very rapid pulse, etc. The phenomena observed in drowning suggested that some light might be thrown on the subject by experiments made along similar lines.

Protocols.—The following technic was employed in the experiments: The animals were placed under full surgical anesthesia, the trachea dissected out, and a cannula tied firmly into it; a heavy tubing was then tied on the cannula, and this was connected with a strong leather bellows, from which a large quantity of air might be suddenly or slowly driven into the lungs—that is to

say, the intrabronchopulmonary pressure might be increased, as would be the case in increased barometric pressure. The blood pressure was taken in the carotid artery. The respirations were neglected, as they could express nothing in such experiments.

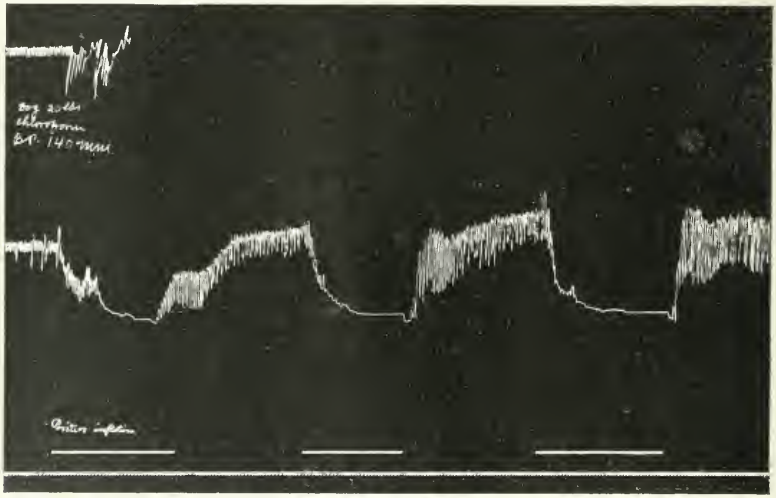
1. A fox terrier, weighing twenty pounds, in good condition, with an initial blood pressure of one hundred and forty-six millimeters, was subjected to the experiments as outlined. The bellows was suddenly emptied into the pulmonary tract of the dog, producing a very great immediate fall in the blood-pressure. The rubber tubing at the close of the injection of the air was clamped, the bellows refilled; then, again as the air was passing into the tube, it was unclamped, and more air forced into the lungs. In this manner the blood-pressure fell abruptly to the abscissa line. The animal was killed almost instantly thereby. An immediate autopsy showed the right heart to be engorged, the left heart empty.

2. A spaniel, weighing twenty-four pounds was subjected to an experiment similar to the preceding; the blood-pressure suffered a staggering fall, as before. In this instant the pressure at the first blast dropped almost to the abscissa line. On removing the clip and allowing the air to escape from the lungs, the blood-pressure leaped up very rapidly, and soon regained its normal height. This was several times repeated, so that there could be no doubt as to the striking effect of an increased intrathoracic pressure upon the circulation. The animal was then killed by again increasing the intrathoracic pressure so as to block the circulation through the lungs. The autopsy revealed conditions similar to those observed in the preceding case.

3. A bulldog, weighing forty pounds, was subjected to an experiment similar to the preceding, with practically the same results. The animal was killed almost instantly. Observations at the autopsy were similar to the preceding.

4. In a strong shepherd dog a control was made by several vigorous blasts from the bellows, producing collapse in the blood-pressure. The air was immediately allowed to escape, and the blood-pressure mounted up again to a point previously occupied. Then, passing a scalpel between the ribs and severing the descending vena cava, the blood gushed in torrents out of this vessel. The blood-pressure sank, but it sank more gradually than in the case of increased intrapulmonary pressure produced immediately before by the injection of the air.

Fig. 1.



Positive inflation of the lungs increasing the trachea-pulmonary pressure by means of a bellows.—Note the momentary rise in the blood-pressure, followed by an immediate staggering fall. The lower line indicates seconds.

5. A large St. Bernard was subjected to the same treatment as in the foregoing case. After producing the collapse in the blood-pressure by forcing air into the lungs and then allowing the blood-pressure to recover itself, the inferior vena cava was severed and the blood permitted to gush forth freely. A great fall in blood-pressure was produced, but this fall was not so sudden nor was the collapse so marked as in the experiment in forcing in air.

Summary of Experimental Evidence.—The evidence of these experiments and of the experiments on drowning tends to show that a sufficient increase in the intrapulmonary pressure may produce a collapse of the circulation. It robs the left heart directly of blood, and, therefore, causes a

greater collapse than can be produced by severing either the superior or the inferior vena cava alone. Now, as a workman enters a tunnel under high barometric pressure the respiratory tract is subjected to an increase in pressure, and the immediate symptoms may be interpreted from this main

Fig. 2.

Read from left to right. The white lines below the blood-pressure indicate the length of time of the application of the force. The lower line indicates seconds. The fall in the blood-pressure was caused by forcing air into the trachea by means of a bellows. In each succeeding experiment the air was forced in more suddenly. Note the quick recovery in each instance when the bellows was released. The curves could be varied at will by applying varying degrees of force in the inflation.

fact. The dizziness, the difficult breathing, the soft, rapid pulse, all would be produced by a great fall in the blood-pressure. The respiratory symptoms may be produced by a sudden fall in the blood-pressure as well as diminished circulation of the blood, thereby diminishing the exchange of gas in the lungs, which, in itself, is sufficient to cause an increased respiratory action and produce the respiratory distress.

II. Foreign Bodies in the Pharynx and Esophagus.

Preliminary Remarks.—The symptoms produced by foreign bodies of considerable size lodged in the pharnyx and certain portions of the esophagus bear a close resemblance to those occasioned by the presence of foreign bodies in certain parts of the respiratory tract. Among the symptoms of choking may be mentioned cyanosis, asphyxia, collapse and slow pulse. These symptoms so closely resemble those produced by foreign bodies in the larynx that the one condition has been frequently mistaken for the other, and in many cases the differential diagnosis from the subjective symptoms alone has been quite impossible.

The following research was undertaken to attempt an explanation of these phenomena:

Protocols.—1. On a mongrel dog, weighing twenty-eight pounds, whose blood-pressure registered one hundred and thirty-four millimeters, under anesthesia, the following experiments were performed: (a) The esophagus was exposed by careful dissection, so as to avoid severing any of the nerves. This was then opened by a longitudinal slit in its middle, and the portions immediately above and below the slit were subjected to dilatation by means of a large bulb and also with a uterine dilator. Although the dilatation was forcible no effect upon blood-pressure was produced. It is doubtful whether the slight slowing of the respiration was a coincidence or an effect. (b) Then passing the instruments down to a point opposite the bifurcation of the trachea and producing there a similar dilatation, like observations were made. (c) The instruments were passed upward to a point opposite the larynx and dilatation was made; there was a slight rise in blood-pressure

Fig. 3.

Experiment on choking, by pressing a globular foreign body into the esophagus opposite the larynx.—Note the temporary inhibition of the respiration (upper tracing) and the staggering fall in the blood pressure (second tracing).

and a temporary arrest in respiration occurred, this temporary arrest being followed by slow respiratory efforts during the remainder of the dilatation. (d) The same experiments were repeated with similar results. Then passing the dilator down to the cardiac orifice of the esophagus and

dilating this tube, there was produced a slight fall of blood-pressure, and the respirations were diminished in frequency. (e) On introducing from below upward the rounded handle of an instrument larger than the opening into the pharynx, producing thereby as great a dilatation as possible of the upper portion of the esophagus, there followed a very marked fall in blood-pressure, and the character of the heart beats displayed the distinct effect of "vagal" action. The respirations at the same time were very much slowed. The middle portion of the esophagus was then again dilated with as much force as possible, resulting in a slight irregularity of respiration with an unchanged blood-pressure curve. (f) Forcible dilatation of the esophagus, again upon a level with the upper portion of the larynx and at the end of the pharynx, produced a very great immediate fall of the blood-pressure and complete arrest of respiration. The narrowest portions of the esophageal tube were at the pharyngeal and the cardiac extremities.

2. On a mongrel dog, in poor condition, weighing twenty-three pounds, under ether anesthesia, the following experiments were performed: (a) Introduction of the rounded, wooden handle of an instrument into the pharynx produced a marked "vagal" cardiac action and irregular, slowed respirations. This was twice repeated, with the same result each time. The middle portion of the esophagus was again dilated, and it was found that but minor effects were produced from as little or as much dilatation as was possible of this tube from the lower level of the larynx down to near the cardiac orifice. (b) On forcing an obturator into the esophagus very slowly upward until it entered the cavity of the mouth, no appreciable effects were produced until it reached a point opposite the upper half of the larynx, when a marked fall in the blood-pressure occurred and temporary respiratory arrest. (c) An injection of atropine in sufficient dose, as proven by Du Bois-Raymond, to paralyze the nerve endings of the vagi was given. Then, on repeating the dilatation or choking in the area opposite the upper portion of the larynx and in the pharynx, no effect upon the blood-pressure was observed; the respirations were arrested as before.

3. On a Newfoundland dog, weighing forty pounds, in good condition, with a blood-pressure of one hundred and twenty-eight millimeters, under ether anesthesia, the following experiments were performed: (a) The rounded wooden end of an instrument, larger than the normal opening of the pharynx, was rather forcibly pressed through the mouth into the pharynx. This produced an immediate and very considerable fall in blood-pressure with temporary arrest of respiration, followed by irregular, slow respiratory efforts. Introducing the same into the cardiac end of the esophagus through an incision in the stomach, there was a slight fall in blood-pressure and slightly irregular respirations. Then, by exposing the esophagus in the middle of the neck and making a longitudinal opening, the instrument was passed through this incision upward, forcibly dilating the esophagus at a point opposite the larynx, whereupon there was an immediate and very considerable fall in blood-pressure, with temporary arrest of the heart and of respiration. (b) A physiologic dose of atropine was given, and its efficiency proved in the usual way. Then a repetition of the foregoing experiment produced but little effect upon the blood-pressure, the little being sometimes a fall; but it did not prevent the arrest of respiration.

4. On a bull-dog in good condition, weighing twenty-eight pounds, having a blood-pressure of one hundred and forty-five millimeters under ether anesthesia the following experiments were performed: (a) Forcible dilatation of the esophagus in its middle portion produced a rise in blood-pressure and a slight slowing of respiration. This was repeated twice, in different portions of the esophagus, with like results. (b) The same experiment opposite the upper portion of the larynx produced a marked fall in blood-pressure, with "vagal" beats and temporary arrest of respiration; later on the respirations recovered their normal rhythm. (c) A physiologic dose of atropine, proved in the usual way, prevented the effect upon the heart, as was shown in the preceding case, but the respirations were arrested as before. Now, making sections of both superior laryngeal nerves and repeating the experiment of choking opposite the larynx, there was no effect produced upon either the cardiac or respiratory action. Traction downward on the esophagus produced a fall in the blood-pressure but the characteristic "vagal" beats were not observed and the respirations were unaltered. Traction upward produced a slight rise in blood-pressure, with no alteration in respiration.

5. On a healthy mongrel dog, weighing twenty pounds, blood-pressure one hundred and forty-eight millimeters, under chloroform anesthesia the following experiments were performed: (a) The handle of a chisel passed into the pharynx and forced down in imitation of choking produced a marked fall in the blood-pressure with arrest of respiration. The pressure of the chisel did not come in contact with the larynx but with the pharynx and the base of the tongue. (b) A physiologic dose of atropine prevented the appearance of the blood-pressure phenomena on repetition of the experiments. The respirations were arrested as before. Various portions of the esophagus were then tested, and, with the exception of the cardiac end, there was but little effect upon either the respiration or the blood-pressure. The cardiac end was finally dilated with a Goodell dilator with very great force, the operation resulting in a slight slowing of respiration. Finally on severing both superior laryngeal nerves, then repeating the pharyngeal choking experiment, there was a rise produced in blood-pressure with slight respiratory slowing; upon traction the fall in blood-pressure was much less and there was no respiratory alteration.

6. On a healthy bird-dog, weighing thirty and

one-half pounds, with blood-pressure of ninety-nine millimeters, under chloroform anesthesia, the following experiments were performed: (a) The wooden handle of an instrument was placed deep in the pharynx, and the free end carried outward into the angle of the mouth so as to produce a severe prying pressure against the walls of the pharynx. This produced a staggering fall in the blood-pressure, with complete temporary arrest of the heart and of the respiration. On severing both superior laryngeal nerves and repeating the experiment there was a very marked fall in the blood-pressure, with temporary arrest of the heart as before, but the respirations remained unaltered. (b) Division of the hypoglossal nerves on both sides and repeating the experiment produced a temporary arrest of the heart, with a staggering fall of the blood-pressure, but no effect upon the respiration. (c) As a control, very severe intralaryngeal manipulations were made. These produced no effect on either the respiration or the heart's action. Then choking was again done in the same violent way, through the mouth with the wooden handle of an instrument, producing thereby the same inhibition of the heart as before.

7. On a thirty-nine-pound dog, with blood-pressure at one hundred and ten millimeters, in poor condition, under chloroform anesthesia, the following experiments were performed: The glossopharyngeal, the hypoglossal, and the superior laryngeal nerves on each side were exposed, looped with thread, and the animal prepared for the following tests: (a) As a control, the animal was choked from below upward, opposite the upper portion of the larynx, with the production of the usual inhibitory phenomena; then pharyngeal choking was practised through the mouth with the usual force, and resulted in the usual inhibitory phenomena. (b) Both glossopharyngeal nerves were then severed. On repeating the above control manipulation, similar inhibitory phenomena were produced. (c) Division of both the hypoglossal nerves and then repeating the choking experiments produced practically the same reflex phenomena upon both the respiration and the heart. (d) After an injection of one-one-hundredth of a grain of atropine into the jugular vein, repetition of the same experiments produced no effect upon either the respiration or the heart's action. In the experiment of choking, especially when the foreign body was large, there was evidence that the vagus itself was mechanically stimulated, either directly by a direct continuity of pressure, or indirectly by being dragged on by structures that had a connecting anatomical relation with it, and that thereby a direct inhibition was produced.

Summary of Experimental Evidence.—It is noted in all the cases that the narrowest portions of the pharyngo-esophageal tract were at the pharyngeal and the gastric ends of the tube respectively. Artificial choking produced at the gastric end of the esophagus had some effect upon the respiration, usually slowing it, and caused also some fall in the blood-pressure, but in no case were the effects of a striking nature. They were properly classed as minor phenomena. In no experiment on any part of the esophageal tract up to a point opposite the larynx were more than minor effects produced. Severe dilatation of this portion of the tube sometimes produced a rise, sometimes a fall, in the blood-pressure; the respiratory effects were never of much importance. However, at the points opposite the larynx, especially the upper part of the larynx, very marked respiratory and circulatory phenomena were caused by artificial choking. These effects were doubtless inhibitory and were produced through the vagus.

That the cardiac action was through the vagus is proved by the fact that physiologic dosage of atropine in every case prevented the fall in blood-pressure and the "vagal" strokes. That the superior laryngeal nerve was not the only path over which the inhibiting impules passed is proved by the fact that the pharyngeal choking, especially when accompanied by considerable violence, produced a marked fall—in fact, a collapse—in blood-pressure after the superior laryngeal had been severed. That it was not through the hypoglossal or the glossopharyngeal that this collapse was produced was proved by the observation that the same phenomena occurred after their severance.

Direct observation of the mechanical dragging on the upper portion of the vagus through the medium of the numerous anatomical structures lying in such close apposition to it and so closely interwoven, together with the negative proof adduced by the experiments, was sufficient to show that a part at least of the inhibition phenomena were due to a mechanical irritation of the superior laryngeal; but that it was not the only tract over which impulses passed was proved by a slight alteration in the respiratory action after the superior laryngeal had been severed, although no such marked effects as before could be produced. It is true, however, that all the evidence goes to show that the superior laryngeal is the only source through which choking may cause very striking reflex inhibition of the respiration. Tolerance, so far as the respirations are concerned, is very soon acquired; it is later acquired on the part of the circulation.

Some Observations.—Choking, then, produced symptoms of reflex inhibition, partly through the superior laryngeal and partly through the trunk of the vagus itself. In the case of the larynx all the symptoms are due to mechanical stimulation of the superior laryngeal nerves. In a given case, then, of threatened asphyxia, if operative procedures are to be undertaken for dislodgment of a foreign body, it would be well to give the preliminary dosage of atropine to prevent a great collapse or possible death during the operative procedures. It is perfectly apparent that in cases in which there is a history of choking without inhibition phenomena the foreign body, if large enough to cause much pressure, must be at a point below the level of the larynx.

(To be Continued.)

CLINICAL MEMORANDUM.

HERNIA IN PREGNANCY AND PREGNANCY IN HERNIÆ, WITH NOTE ON UMBILICAL HERNIA.[1]

BY THOMAS H. MANLEY, M.D.,
OF NEW YORK.

HERNIA during or antecedent to the pregnant state we sometimes see, and there are recorded cases of impregnated herniæ; *i.e.*, when the uterus lies outside the abdomen in a hernial sac. The greater number of modern works on obstetrics and gynecology are silent on the subject of hernia as a complicating factor, or an accident in maternity or delivery. This is somewhat remarkable because the surgery of obstetrics has undergone great expansion of late years, and gynecology has come to claim the lower abdominal areas as belonging to its domain in addition to the open passages and pelvic viscera. The fully equipped obstetrician of our time must be skilled in operative-surgery, and hence prepared to deal with complications which, like herniæ, so frequently attend maternity. Therefore we would be led to believe on a review of the subject that, as the surgeon is somewhat chary about encroaching on the preserves of the gynecologist, and the latter hesitates to include any type of hernia as coming within his legitimate field, some doubts remain whether obstetric hernia belongs to the province of the latter or the former. But, however this feature of the question may be decided, the fact remains that as far as can be learned neither one up to this time has dealt with the subject with the fulness its importance merits. As has been demonstrated the evolution and pathology of this infirmity exhibits special and characteristic features in the female, and as we advance a step further we will observe that during the function of procreation it presents many remarkable and unique phases. For many cogent reasons it is important to determine what influence pregnancy has on this disease as a whole; whether it augments or retards it. Many of our most noted and eminent authorities of the past strenuously maintained that conception and child-bearing exercise a salutary influence on certain diseases and tendencies to disease, some including hernia in this category. In order to decide this and be able to judiciously advise those females who suffer from this infirmity and contemplate matrimony, it is necessary not only to listen to the testimony of our own contemporaries, but also to turn to those whose experience best entitles them to be heard on this important aspect of hernia.

In discussing this topic, Gurdieu, a noted obstetrician in the early part of this century, observes that "there are two causes which dispose the pregnant female to hernia, one is a relaxed softened state of the muscle fibers, with an excess of fluid in the tissues, the other is the weight of the gravid uterus on the intestines." He further notes that one who had hernia in childhood is prone to its return in pregnancy, but after delivery it tends to disappear. He fails to specify the types alluded to. Kuhn who gave special attention to ruptures in pregnancy, maintained that for some months after conception small reducible ruptures tend to recede as the uterus rises out of the pelvis; in this way many permanent cures were affected. He further showed that when relapse occurred a fresh protrusion of the peritoneum came down and the old degenerate sac, now distended with fluid, lay in close contact with it. My own experience has been that groin ruptures as a general rule are neither produced nor aggravated by child-bearing. In those cases known by the laity as "falling of the womb," it was a custom with many practitioners in the past to encourage pregnancy as a probable cure. In my own opinion there are certainly no valid grounds for prohibiting marriage in simple groin ruptures, as we have no positive proof that they are produced by child-bearing, although diminutive femoral herniæ are probably aggravated by it. But navel ruptures often greatly augment in volume during pregnancy, if they are not sometimes produced by it, and with repeated confinements may attain enormous proportions.

The uterus is sometimes lodged in the sac of a hernia and may there become impregnated. Fothergill says, "The uterus occasionally is lodged in the sac of an umbilical, femoral or inguinal hernia, where it may become impregnated; in which case an abortion may be induced and the hernia reduced or hysterectomy may be performed." Simon and Sabitier both report instances of impregnation of the uterus which had escaped through the inguinal and femoral portals, these sometimes advancing to term. Impregnation of the uterus in umbilical and ventral herniæ is not so very unusual. But what shall be done in the event of the impregnation of the uterus in a hernia of the groin? The simplest, safest and quickest relief would be obtained by a hysterectomy, but this would violate one of the moral foundations of surgical science. As early as 1531 Nicolaus Pol, an Italian physician, removed a mature infant from a massive labial hernia, the mother sinking on the fifth day and the child surviving. In 1761 Gowey, a Rouen surgeon was visited by a young lady of society, whom he had reason to suspect was suffering from an infected bubo. At the end of four months, as it was steadily increasing in size, he decided to open it, and on doing so found a living fetus. He baptized it and cut the cord. The result is not stated. Sylvester Saxtorph, a Dutch practitioner, records a unique case of this description in a poor peasant woman who previously had four normal labors. The gravid uterus escaped through the abdominal wall and hung down below the knees, but it was observed that a very thick, broad pedicle projection passed up through it into the abdomen. The case was seen by several of the most noted physicians of Holland, but none ven-

[1] Abstract of a paper read at the Annual Meeting of the Mississippi Valley Medical Association, held at Chicago, October 3-6, 1899.

tured to interfere. She went on to term when the uterus became the site of violent contractions, sent the fetus up through abdominal portal and down, out and alive through the natural passages. He followed up the contracting uterus, pressed it inside and there it remained. He writes that the point of the emergence of the hernia was not a normal canal, but an opening through the muscles.

Most writers on this strange freak note that, as in all ectopic pregnancies, there is an invariable tendency to early abortion. Cazeaux, in 1840, cited a case of this class occurring in a young woman, twenty-four years old, pregnant for the sixth time. Pregnancy continued to the eighth month when the parts were opened and the infant delivered, both mother and child being saved.

Maternity and Exomphalos.—All are familiar with the influence in exomphalos as a causative factor. Umbilical herniæ of large dimensions we rarely see, except in child-bearing women. Whether alone, *ab initio*, pregnancy produces exomphalos there are some good reasons to doubt, but no one can deny that it leads all others as an aggravating factor. In some cases the whole umbilical opening gives and practically all the contents of the abdomen make their way out into this accessory cavity. In many the investing integument becomes so wasted that the vermicular movements of the intestines may be plainly felt, and cases are on record in which the atrophied integument has given way during the violent muscular contraction of labor, and the intestines were projected outward through the breach. This type of hernia presents many complicating, troublesome and dangerous features. It is one variety which never undergoes spontaneous cure. It is difficult or impossible to control by mechanical support; is prone to erosion, hemorrhage and incarceration, and is rarely completely reducible. It is one of the herniæ liable to impregnation, when it partly or entirely includes the uterus. Bedford has published the particulars of a case in which the head of the fetus was caught at the neck by the annular collar of the navel. The head was outside but by cautious taxis the constriction was overcome and the head forced back into the abdomen. Murray has seen an umbilical extrusion contain a fetus of the eighth month. In one of my own cases, that of a negress, there was in addition to the uterus a mass of fibroid outgrowths in the hernial sac.

Strangulation and the Pregnant State.—At first it would strike one as self-evident and conclusive that, in a woman with hernia, every delivery must entail a great risk, and the throes of labor must lead to a marked augmentation in volume of the hernia and a tendency to intestinal strangulation. Landis declares that "in hernia, especially of the non-reducible type, there is great danger of strangulation during labor," and Barnes affirms that "although hernia may not obstruct labor, it may become a serious source of danger to the mother." That pregnancy is an aggravating factor of various types of hernia all will concede, but experience and medical history prove beyond question that labor and simultaneous strangulation are incompatible conditions. No such case has come to my knowledge nor can I find a single case of labor at term complicated by strangulation in the annals of medicine on record. This would go to demonstrate clearly that mechanical pressure, under all circumstances, is only one factor in the production of strangulation, and it may be but a coincidence. Bedford raised the question as to what should be done in inguinal or femoral hernia in labor where with each pain the mass is vastly augmented; whether, in view of possible strangulation, we should be content to keep the hernia in check by manual pressure, or hasten delivery by artificial means.

We are in possession of no evidence that the gravid uterus is ever a cause of strangulation; on the contrary, advanced pregnancy rather serves as a deterrent. Several cases of strangulation during pregnancy are scattered through modern literature. These were evidently all early, as the subjects are reported to have quite generally "miscarried or aborted after operation." Unna reports one, a woman of thirty-seven, with femoral strangulated hernia and gangrene of the intestine. Artificial anus. Miscarriage on fifteenth day. Reavray and Jollivet each report cases in the third month of pregnancy with femoral strangulated herniæ. Kelotomy. Abortion on twenty-first day; death on twenty-seventh day. Mr. Canton reports a case of strangulated femoral hernia in the fourth month of pregnancy. Kelotomy was performed; miscarriage and death the same night. Dr. W. B. Fletcher of Cincinnati, O., has reported two cases. One miscarried on the tenth day after kelotomy for femoral hernia. His second patient was pregnant four months and was operated on for strangulated femoral hernia. Miscarried ten days later, but recovered. Weiner operated on another case in a patient thirty-seven years old, with femoral hernia. Pregnant three months. Miscarried on third day. Recovered. It is rather curious to note the absence of records of strangulated exomphalos in pregnant females in recent surgical literature, although, nearly a century ago, such cases were successfully treated by kelotomy and reduction. Chelius records three cases of strangulated umbilical hernia in pregnant women. Cooper's patient was in the eighth month of pregnancy, Lawrence's in the eighth month, and Clement's in the third month. Kelotomy was performed in each case with recovery.

Herniated Conditions in the Female.—In the early part of the past summer, 1899, two cases which aroused my interest came under my care for treatment. They presented pathologic states, which, up to the present time, have not received systematic study. My patients were both young women under thirty; one the mother of one child, and the other of two children. They were both in good health and were neither corpulent nor over-stout. They came to ascertain if anything could be done for a giving-way or a marked pro-

lapse forward of their abdomens which had followed their confinements. One of the patients came from Brooklyn and her family physician had taken her to one of the most noted surgeons of that city, who pronounced "the pot belly" due to excessive fat. This examination must have been a superficial one, for on exposure and careful manipulation, it was found that over the most prominent part of the abdomen there was neither adipose tissue nor muscle, for under the thin, wasted, projecting pouch the peristaltic move-

Fig. 1.

Before Operation.

ments of the intestines could be easily made out. It seemed as though the whole musculature of the lower and lateral walls had given way and the muscles been resorbed, for nothing remained but a thin baggy envelope of fibrous structure, under a wrinkled, atrophied integument. The other case presented similar features. Both were particularly desirous for relief from the ungainly deformity which they possessed. It was my conviction in both cases that nothing curative could be promised, as degenerative and disintegrating changes had involved the muscle elements and destroyed them beyond any hope of repair.

The etiology and pathology of this unfortunate state must be of great importance to the obstetrician, for the probabilities are that the only effective therapy, if any, must come through prophylaxis, which should consist of a properly adjusted broad belt to be worn through the latter part of the pregnancy. Anything which produces very marked intra-abdominal pressure may lead to extensive atrophic changes in the muscles of the abdominal walls. Thus I could not find, on autopsy, a muscle fiber in the wasted sheath of the recti or lateral oblique of the abdominal wall in a woman who had for many years been subject to a large uterine fibroid. The violence of rapid labors, or the effects of those that are tedious and protracted, may tear the muscles from their attachments or widely sunder the central raphe below the umbilicus and thus produce a diverticulum or diastasis of the recti. Thereafter central bulging of the abdominal walls follows, into which abdominal organs tend to gravitate. This furnishes the basis of visceral ectopia, enteroptosis, with displacement of the liver, spleen or kidney. The full integrity of the abdominal walls is forever destroyed and all the elements of true hernia are present to remain.

Relative to its frequency, McCready found 61 cases of hernia in the examination of 3625 females in the London Truss Society from 1888 to 1890. In the aggravated cases, he adds, "the muscles quite disappear. This allows the abdominal contents to undergo displacement and topple over the pubis in a bag-like pouch, the shape, position and volume depending on the situation and extent of muscular damage." It is somewhat remarkable that more attention is not given to this subject in the text-books of obstetrics or gynecology, and I do not find any reference to it at all in the most of the later works on surgery. In Curtis' admirable treatise, however, we do observe that this important lesion did not entirely escape the author, for he says that "a separation of the rectus muscles produces a form of ventral hernia which is seen after pregnancy in

Fig. 2.

After Operation.

those who have been delivered at term." This type of the infirmity derives its great interest from the points of view of prophylaxis, causation, lack of tendency to strangulation or incarceration. Its progressive increase is quite beyond surgical relief and is rather incoercible to prothetic support.

Patient, a female aged forty-nine years; married; mother of six children. No history of trauma or hereditary tendency. She noticed the present exomphacele after the birth of her third

child. It continued to gradually increase in volume, although it never gave her much inconvenience or worry until about six months previously, when the surface became eroded and began to bleed. In January, 1896, she was sent to me from Wilkesbarre, Pa., by Dr. A. P. O'Malley, for omphalectomy.

I found her an active, vigorous woman. There were no symptoms pointing to intestinal complication, and on examination is was evident that the extrusion consisted of an epiplocele. The integument over it had become as thin as parchment, with striated cicatrices radiating downward. The mass was entirely irreducible. Considering the character of the hernia and the general condition, it seemed to promise a most successful issue after operation.

The operation consisted in making a double elliptical incision along the lateral planes of the stem of the tumor. Then a free opening was made to the peritoneal cavity and the whole mass drawn well forward. It was caught at the root, secured at the base, and firmly held with strong forceps. Division was made though very cautiously and the numerous vessels secured separately by five silk sutures. When division was complete the lateral peritoneal edges were drawn well over the large nude stump and closed securely with a double row of continued catgut sutures. Then the stump was dropped back into the peritoneal cavity and the opening near the umbilical aperture was closed by heavy, through-and-through silk sutures. Recovery was rapid and she left for home three weeks after the operation at St. Mark's Hospital.

MEDICAL PROGRESS.

Mercurial Inhalations.—It has for a long time been held that the mercury vapors arising from the inunctions given to syphilitics had more marked therapeutic effect when inhaled than the small amount of the drug which was absorbed by the skin. Working on this fact for a basis, R. Kutner (*Berlin klin. Woch.*, Jan. 8, 1900) describes an apparatus invented by himself for the better administration of mercury by inhalation. Roughly explained, his method may be stated as follows: A closed box, in which there is an arrangement whereby the patient can work the mechanism, is provided with a tube which leads to a mouthpiece. The mechanism provides for the rubbing of mercurial ointment within the box over successively changing surfaces while the patient remains with the mouthpiece in position over his nose and mouth. It can easily be seen how advantageous such a method of administering a disagreeable remedy would prove. Not only is the skin unaffected and the attendant discomfitures and annoyances prevented, but the dosage is better regulated and none of the vapor passes off uselessly into the surrounding atmosphere. Furthermore, it is far more likely that patients become affected with stomatitis from breathing continuously the vapor arising from the old inunction method, than from absorbing the vapor several times daily, even although at these times the dose is more concentrated and powerful. The most important consideration, however, bearing on the therapeutic value of this method of administration is whether a sufficient quantity of mercury can be inspired in a sufficiently short period of time to be of positive value. Our author says that there is no question of this whatever. He states that with one half-hourly inhalation daily a noticeable amount of mercury can be demonstrated and recovered from the urine after a few days. This proves conclusively that the method is of practical utility. Symptoms of mercurialism were never noticed but Kutner insisted on the use of chlorate of potash as a gargle regularly after each inhalation. In one or two patients, indeed, in whom previous inunctions had resulted in gingivitis, the present inhalation method gave good results without a trace of poisoning. The author promises further facts regarding the procedures and investigations.

Convulsions after Labor.—When convulsions occur immediately after labor the physician is always more or less in the dark as to their causation and the proper means of relief. Therefore A. K. Bond (*Am. Jour. of Obstet.*, Jan., 1900) reports a case and discusses its etiology and treatment. The patient, twenty-three years of age, had always been very healthy. During the last two months of pregnancy she had had occasionally, on lying down, a twitching of the lower limbs. This would compel her to sit up, whereupon the twitching ceased. She was inclined to be constipated, but kept her bowels open with aperients. On measurement, the pelvis was found to be about one-half inch deficient in each of its dimensions. The urine was normal. There was no dropsy. During the whole of the first and second stages of labor the patient repeatedly vomited bile-stained matter. The labor was slow and it was finally necessary to deliver the child with forceps, because of the large size of the head and the small pelvis. A perineal tear required three sutures. There was very little hemorrhage during delivery, the uterus contracted well, and the pulse and temperature were satisfactory. The patient complained of headache a few hours later, and about ten hours after delivery had a severe convulsion. The temperature was 100.5° F., pulse 120 and hard, and respiration 28. Urine was abundant and normal, except that it showed a slight trace of albumin, due, as was supposed, to the preceeding convulsive state. Patient was conscious and had persistent headache. The patient seemed to be suffering from an acute intestinal poisoning. Seven or eight more convulsions occurred during the next four hours, although large doses of chloral and potassium bromide were given. There was occasional vomiting so that probably but little of the chloral mixture was retained. Finally, venesection was

resorted to and about three ounces of blood drawn. There were no convulsions after the bleeding. The patient was then given croton oil, calomel, and a strong vegetable cathartic, at intervals, and after one foul-smelling passage and several easy ones, she was free from nausea and headache. On the third day milk came freely in both breasts. The urine was normal. For about two weeks there was an elevation of temperature, which was considered to be a "surgical fever" from the laceration of the cervix and perineum. The lochial discharge was never offensive. Bond thinks that the predisposing cause in this case was the nerve exhaustion of a severe, protracted instrumental labor and the immediate cause an acute stercoremia. He believes that sufficient venesection to lower the arterial pressure and just enough croton oil to carry off the septic mass was the correct treatment for stopping the convulsions.

Intra-abdominal Hernia.—W. Meyer had recently an opportunity to study two cases of retroperineal hernia of the right side. In both patients the cecum was placed unusually high so that the root of the mesentery of the small intestine extended almost transversely across the spinal column. Just below the root of the mesentery, and about midway between the cecum and the vertebræ, there was a pocket with its mouth opening upward. This pouch, situated like an open hand-bag just below the small intestine, was capable of receiving into its cavity the whole of the small intestine from the beginning of the jejunum to the end of the ileum. Indeed, the difficulty with which the intestine escaped from this receptacle caused symptoms of strangulation and led to operation. Meyer explained the development of this pouch by supposing that a hernia had formed in a parajejunal recess. Such a hernia instead of pressing to the right between the mesentery and the posterior abdominal wall, as would be the natural course of its development, grew downward on account of the horizontal position of the mesentery. As time went on, the weight of the contained intestine dragged and stretched the sac, until it reached well over the pelvic brim. One patient whose symptoms of strangulation had lasted not more than eight hours, died on the table ten minutes after the beginning of the operation. The condition of affairs was readily recognized, and the surgeon was engaged in withdrawing the reddened coils of gut when death took place. Ether was the anesthetic employed. The other patient who had suffered for two days with symptoms of obstruction made a prompt recovery from operation. (*Deutsch. Zeit. f. Chir.*, Vol. 53, p. 547.)

Edema of Skin in Influenza.—A new manifestation of influenza has been noted by A. Rieger (*Münch. med. Woch.*, Jan. 2, 1900). A severe pruritus of the head and face was present among the prodromal symptoms. With the full development of the disease a remarkable edema of the scalp appeared. The skin did not appear hyperemic as in erysipelas, but the enormously distended veins gave evidence of a passive congestion. The swelling eventually involved the cheeks and nose, but did not implicate the lower jaw. The original areas soon returned to normal as the face became involved. The condition was complicated by a well-marked fever, which terminated with the disappearance of the effusion. A slight pustulation, but no desquamation, followed this peculiar form of influenza, which, the author thinks, was due to a peculiar concentration of the poison in the skin.

New Guaiacol Preparation.—The numerous disadvantages of which the original antiphthisical drugs creosote and guaiacol are possessed have led modern therapy to employ such substitutes as benzosol, duotal, etc. These, being insoluble and improperly absorbed, reach the foci in too attenuated a form to develop the proper antitoxic effect necessary. A. Einhorn (*Münch. med. Woch.*, Jan. 2, 1900) finds diethyl-glycocoll-guaiacol to be an easily soluble salt which promises to replace creosote and its derivatives since it lacks their undesirable properties. Experiments on animals have proven this salt to be non-poisonous and non-irritating in moderate concentration. In its antiseptic powers it equals boric acid and is also slightly anesthetic. Even in daily doses of 3-12 gms. (45-180 grains) in wafers, or by hypodermic injection, no deleterious effects on the system were noted. The large doses in which this drug may be prescribed are an advantage, since thus a thorough saturation of the body is assured. In addition to pulmonary tuberculosis, encouraging results have been achieved in tuberculous diarrheas and locally in ozena, sarcomatous, carcinomatous and syphilitic ulcers, stomatitis, chronic conjunctivitis, empyema alveolaris, and as irrigations in pyloric stenosis and bladder inflammation.

Otitis Media in Infancy.—Physicians are probably called to attend children for gastro-enteric disturbances more often than for any other cause. E. H. Pomeroy (*Boston Med. and Surg. Jour.*, Jan. 18, 1900) thinks that most of the diseases of childhood are more easily demonstrated to be of infectious origin than can be proven in adults; that the pharyngeal postnasal chamber is the distributing point for infection of the middle ear, the lung, the brain, the stomach, and the intestines; and that the middle ear is an incubator promoting general toxic disturbance in many cases of localized infectious disease. He presents, and discusses at some length, statistics of Ponfick, who made 100 autopsies upon infants dying of congenital heart disease, extensive burns, non-infectious dermatitis, infectious dermatitis, diphtheria, scarlatina, pneumonia, meningitis, gastro-enteritis, otitis media, otitis media with acute bronchitis, chronic tuberculosis, and congenital syphilis. Although otitis media was not suspected in the majority of these cases, it was found to have been present in all except nine. He also cites the results obtained by other investiga-

tors, showing the frequency of otitis in infants. A strong plea is made for the routine examination of infants' ears in all cases of grave disease, as otitis is undoubtedly an astonishingly frequent, and a very serious complication. Pomeroy cites five cases showing the advantage of routine examination of the ears in cases in which the ears apparently have nothing to do with the general condition. In one case no examination of the ears was made, but an autopsy showed otitis media. The ears of the other four cases were examined, otitis discovered, the membrane punctured, and one to four drops of pus liberated. This was followed by almost immediate recovery. Of these five cases, two presented the symptoms of gastro-enteric disturbance alone, one of gastro-enteric disturbance with bronchopneumonia, one was simply fretful with almost imperceptible pulse, and was constipated, and one had vomiting, a temperature of 103° F., and a cough which always caused crying.

Conjunctivitis Neonatorum.—Ammon (*Münch. med. Woch.*, Jan. 2, 1900) doubts that all cases of gonorrheal ophthalmia are due to infection during birth since so many cases develop later than the incubation period would allow. They are to be traced in many cases to poor hygienic surroundings, which favor post-natal infection. Gonococci were not present in all cases; some of the severe ones gave staphlyococci, while the pneumococcus appeared to be the exciting cause in some forms which improved as if by crisis. The pneumobacillus and the pseudoform of the Neisser coccus were isolated in several instances. In discussing the treatment, mention is made of the unreliability of silver nitrate since its powers of penetrating into the deeper layers of epithelium are at best very slight. Protargol has likewise proven itself untrustworthy in this direction and the proper drug has yet to be discovered. A mild antiphlogistic treatment, such as frequent irrigation with normal salt solution and the application of cold pads to the lids, is attended with the best results. After the acute stage is over, protargol may be used as instillation and the sound eye may be prophylactically treated by the same drug.

Slipped Knee-joint Cartilage.—W. H. Bennett (*Lancet*, Jan. 6, 1900) after a careful study of 200 cases of slipped meniscus gives these data: 182 males; 18 females; left knee 133; right 67; inner side of knee 155 and outer side in 45 cases. Patients ranged from thirteen to sixty-two years of age. The symptoms are precise; sudden pain, fixation at varying angle, effusion into joint and tenderness over the damaged cartilage. These symptoms may appear during normal movements, or after a wrench or blow, rotation of the leg upon the thigh being a prominent causative factor. Reduction may be spontaneous, or may follow manipulation. The fulness felt along the cartilage is due to extravasated blood or inflammatory exudation rather than to projecting cartilage. The only positive sign of displacement is the existence of a deficiency just above the head of the tibia in such cases as inward dislocation. Closely related to "slipped meniscus," but not mentioned in surgical literature, is another condition, a bruising of the periphery of the cartilage without displacement or loosening but with local blood effusion and later some inflammatory exudate which work between the bone-ends, and act as a foreign body. In this condition the attack is usually mild, the limitation of movement is slight, but reduction cannot be accomplished nor can the leg be fully extended, results easily explained by referring to the pathological state. Return to full function in these cases is always gradual, *pari passu* with absorption of the exudate about the periphery of the cartilage. Prolonged attempts at reduction aggravate the local condition. Treatment may be subdivided as follows: (1) Temporary rest, massage and exercise after reduction, or after satisfying oneself that the cartilage is simply "bruised" and, therefore, reduction impossible. The joint should be kept at rest for from four to seven days, with a splint. During this period the effusion usually disappears and until it has gone no movement should be permitted. Massage of the muscles and joint without movement cannot be commenced too soon. It prevents muscle atrophy and flaccidity of the joint capsule which is a frequent cause of failure in the treatment, and it expedites the absorption of the effusion. After the effusion is gone, passive movement, without rotary motion, is commenced. A week later active walking, with stiff knee, and after the third or fourth week ordinary walking is permitted. Massage must be continued three weeks to six months, according to the condition of the thigh muscles and the joint capsule, since these must have good tone in order to prevent the joint from wabbling. The iliotibial band is an important factor in maintaining the tone of the capsule, therefore attention must be given to the gluteus maximus and tensor fasciæ femoris muscles. This method of treatment sufficed to cure 112 of the 200 patients. (2) Treatment by apparatus is allowable only when the "rational" treatment cannot be carried out, or where it fails to prevent abnormal lateral mobility, and in those cases where there have been frequent recurrences and operation has been rejected. The only satisfactory apparatus is one preventing rotation in the knee-joint. (3) Operative treatment is indicated where palliative treatment has failed or where speedy relief is urgent. The operation of choice is a longitudinal incision over the cartilage followed by excision of the damaged meniscus.

New Method of Gastrostomy.—Desguin (*Ann. de la Société Belge de Chir.*, October-November, 1899) realizing the importance of simplicity in the operation of gastrostomy on an exhausted patient, has devised the following procedure: A flexible silver tube one-third of an inch in diameter is bent at its middle at a right angle. Over one end of this is fitted a soft rubber tube ten

inches long. The diameter of the rubber tube should be slightly less than that of the silver one, so that it may fit tightly upon it. The overlying skin is disinfected before the patient is brought upon the table. He is then given a little chloroform, or, as the author prefers, an injection of cocaine is made. Owing to retraction of the stomach, usually present in such cases, he prefers to make the incision along the left costal margin. With a pair of forceps the stomach is quickly pulled out through the wound. It is opened and the silver tube passed into it. A catgut thread is bound around the mouth of the gastric wound to prevent the stomach from slipping off of the tube. Two silk sutures are then passed, one on either side of the tube, through both lips of the abdominal wound and through the wall of the stomach at a distance from its opening, equal to the thickness of the abdominal wall. By this means a little funnel is formed at the bottom of which the gastric fistula is situated. The abdominal wound is closed by four or six sutures. The tube comes out spontaneously in about ten days. The author draws the following conclusions: (1) It is desirable to convince physicians of the slight risk of gastrostomy if it is performed sufficiently early. (2) It is equally important to emphasize the high mortality of gastrostomy as practised upon cachectic patients in the last stage of inanition. (3) Inanition is due to digestive incapacity from various causes, which is often greatly increased by narcosis. (4) On this account cocaine should be substituted for chloroform. (5) Complicated procedures are out of place with a debilitated patient. (6) The method of operating above described merits adoption on account of its simplicity, and because it does not require a general anesthetic, and permits the immediate nourishment of the patient and lavage if necessary.

Partial Myxedema.—Hertoghe (*Gaz. Heb. de Med. et. Chir.*, Dec. 17, 1899) points out that, while myxedema is well-known and can be readily diagnosticated and treated, there are many degrees between entire thyroid integrity and complete loss of function of this gland, concernwhich greater difficulties will arise. Three features should be borne in mind: (1) The study of the organic and functional characteristics of the parents of children manifestly hypothyroidic; (2) the analysis of true myxedema in the feeblest traces of the hypothyroidic taint; (3) thyroid treatment of conditions suspected to be myxedematous. True myxedema is characterized by premature senescence of the whole organism; this is seen to a lesser degree in mild chronic hypothyroidism. The dominant symptom, however, is an obstinate constipation. This is a lifelong complaint and all the other symptoms are apt to be ascribed to this one trouble. Once the disease is well established the patients are somnolent and easily fatigued and everything physical or mental seems to be beyond their energy Their sleep is poor, they rise early, more wearied than when they lay down, and it is only toward evening that the symptoms abate. The hands are cold, moist and formless, and with a little experience the physician may appreciate the extent of the disease by a mere hand-clasp. In children the most important sign is backwardness. The tendency here is toward cure, but in adult women it is not until the menopause is reached that improvement is noticed. The effects of thyroidine are no less marked than in true myxedema. It should, however, be used with discretion. Alcoholic drinks, tobacco and the excessive use of sugar must be strictly forbidden. The disease is often mistaken for and treated as anemia, and hence wines, beers, baths and cold douches are wrongly prescribed. Thyroid extract is more active and better tolerated after a preliminary treatment by means of the mild alkalis, sodium bicarbonate, etc. Since diarrhea may be caused by this drug, it is well to combine it with bismuth.

Post-partum Hemorrhage.—E. P. Davis (*Med. Rec.*, Jan. 13, 1900) lays considerable stress upon the necessity of appreciating the most frequent causes of post-partum hemorrhage and thus making the treatment less often required and more effectual when it is needed. The chief cause of this dangerous condition is exhaustion of the patient; local exhaustion, which is seen in the relaxed condition of the uterus, and general exhaustion which is observed in those cases of protracted labor in which the mother fails to expel her child spontaneously. The retention of a partially detached placenta, lacerations of the genital tract and profoundly altered conditions of the patient's blood are less frequent causes. Thorough examination should always be made as early as possible to learn the size and condition of the mother's parts and the presentation of the child. To avoid exhaustion during the first stage, the patient should be given liquid foods frequently, allowed to sleep, even if hypnotics are necessary, and the bladder and rectum kept emptied. McLean's double bag will greatly assist in dilating an obstinately firm cervix. In the second stage, mere "signs of exhaustion" are now considered indications for instrumental interference, which should be done under ether. After the expulsion of the placenta an examination of the parts will disclose any cause for hemorrhage in the cervix or vagina and this should at once be sutured in case the hemorrhage is at all severe. Pressure on the uterus and massage should be maintained until the organ is firmly contracted, combined with internal medication of ergot and one-thirtieth of a grain of strychnine sulphate with one-two-hundredth of a grain of atropine. Should the uterus fail to contract a vaginal douche of salt solution at 110° F. will be found very effectual. Should further stimulation be necessary or if retained blood-clots or placenta are thought to be present, a uterine douche of hot salt solution in a one-per-cent. lysol solution may be used combined, when necessary, with the use of the blunt curette. Failing in this, the

uterine cavity should be tamponed with iodoform gauze, but only under the strictest antiseptic precautions. The gauze may remain for from twenty-four to thirty-six hours and its removal should be followed by a gentle but thorough irrigation with decinormal salt solution at 105° to 110° F.

Artificial Production of Gout.—Gout is known to attack birds and other mammals as well as *homo sapiens*. In birds especially the disease is a much-feared one, producing similar uric acid concretions in the joints and lower extremities and affecting the kidneys. H. Kionka (*Berl. klin. Woch.*, Jan. 1, 1900) describes experiments conducted on poultry to produce the gouty diathesis. Although the disease can be produced in birds by means of the internal administration of chromic acid or oxalic acid, the author prefers to obtain the condition by affecting the nutrition. This he did by feeding hens with fresh horseflesh, free of fat, keeping them in a roomy enclosure. They had as much water as they desired. The captives rapidly became accustomed to their meat-diet, and seemed at first to thrive very well. In from three to five months the first symptoms of sickness appeared. These gradually drifted into well-developed gout. Various types of the disease manifested themselves. The hens at first became affected in their movements, unsteady in their gait, falling down when jumping from their roost, dragging up their legs as though in pain when stepping about. Then followed weakness in the limb, swelling of the joints, loss of appetite and unwillingness to move. Between such attacks all the symptoms disappeared only to reappear at successively shorter intervals. All signs and symptoms then became aggravated, the appetite failed completely, the limbs remained swollen and in a short time death ensued. In the more chronic cases the same symptoms were evident but were much longer drawn out. Localized concretions were well marked in the joints and between the tendons of the legs and feet. There were uric acid infarcts in the kidneys and uric acid deposits in the serous membranes. The hens seemed to show, while still alive, a great longing for lime. Two of them were, therefore, fed with 10 grams of pulverized egg-shell daily. Under this influence the excrement of these two birds many days exceeded 500 grams and their thirst was consequently increased. The reaction of their excrement also changed from acid to alkaline, while the quantity of uric acid given off was markedly diminished. The explanation of this may be said to be that the lime enters into combination with the nitrogenous compounds, which otherwise would form uric acid, to form urea and urates. In the human economy it is not impossible that the same processes are due to the same causes, and this opens up a large field for further investigation.

Surgery and Goiter.—G. Reinbach (*Beitr. z. Klin. Chir.*, vol. 25, p. 267) gives the results obtained in Mikulicz's clinic after various operations upon benign goiter. One hundred and sixty-two operations are recorded, with four deaths, giving a mortality of 2.5 per cent. In sixty-three cases enucleation was performed without a death. Three of the deaths after partial resection, were attributable to pneumonia. The fourth death followed ligation of the thyroid arteries. Most of the patients were seen at various times after the operation and only in one instance was there any recurrence of trouble. One patient developed tetanic symptoms after operation, due apparently to the fact that not enough of the thyroid was left to satisfy the needs of the body. The tetanus was of short duration.

Failure of Diphtheria Antitoxin.—During the last few years the antitoxin treatment of diphtheria has been generally accepted by the medical profession as being the most satisfactory, since it was theoretically an ideal one and also on account of the glowing reports which have been made in its favor. Enough time has now elapsed to gain a more accurate knowledge of its true efficacy in general practise and certainly the results are not so good as had been hoped. In the *Medical Record* (Jan. 20, 1900) J. E. Herman has given a rather extended report of statistics and insists upon the uselessness of the antitoxin treatment. He draws a close distinction between the toxin treatment which has proven successful in cases of smallpox, hydrophobia, and sarcoma, and the antitoxin serum which has been used in cases of diphtheria, tetanus, typhoid fever, tuberculosis, etc. He claims that it cannot be shown that any of these antitoxin serums have proven of any decided value, the somewhat lessened mortality in diphtheria being due rather to improved methods of medication and especially intubation than to the use of the antitoxin serum. Intubation is naturally used much earlier than tracheotomy would be, and hence many of the distressing and often fatal symptoms of stenosis are avoided. It is further claimed that the Klebs-Loeffler bacillus has no etiological relation to diphtheria, and many eminent authorities are quoted to show how frequently this bacillus is present in the normal throat or in cases of simple rhinitis or pharyngitis without the peculiar and general symptoms of diphtheria.

Myopia in School Children.—That near-sightedness has markedly increased with civilization and, in fact, is almost unknown among savage races is fully appreciated. The confinement and long hours of eye-strain which school children are now obliged to undergo results in the elongation of the eyeball and consequent myopia. P. A. Callan (*N. Y. Med. Jour.*, Jan. 20, 1900) says that many of the ailments of the school children of to-day are the result of reflex disturbances caused by even a normal eye which is subjected to a long-continued strain, especially during the early development of the child and in the midst of poor hygienic surroundings. He pleads for

shorter hours at school and more outdoor exercise for the children.

Photographing Gall-stones.—Numerous attempts have been made to determine the presence of gall-stones by the use of the Röntgen rays, but authorities are generally agreed that it is impossible. Carl Beck (*N. Y. Med. Jour.*, Jan. 20, 1900) reproduces a number of successful photographs and gives an interesting report of the points upon which success depends. An important consideration is the time of exposure which seems to vary in different cases. He found that the longer the time of exposure the clearer the liver and the more obscure the calculi appeared. About five or six minutes seemed to give the best results, but this must be determined in each case. The most powerful focus tubes were used. It was also found essential that the patient should lie upon the abdomen with a pillow underneath his symphysis and clavicles. Another important point is that the rays shall not penetrate the abdomen in a vertical direction, but should form an angle of about forty-five degrees with the plate. A great deal also depends upon the composition of the stone, which is far more complex than that of renal calculi. Various experiments demonstrated that the calculi consisting of pure cholesterin give but an indistinct shade, while those containing quantities of calcium are well shown. The common biliary calculi are largely composed of cholesterin and hence are so permeable to the rays that only a slight shade is shown. Those calculi which consist of a compound of calcium and bilirubin, or carbonic acid, are very hard and are therefore distinctly brought out by the rays. It is thus found that only in selected cases can the demonstration of the presence of gall-stones be successfully made, but further experiments may improve the technic and furnish more valuable results.

Psoriasis and Glycosuria.—In spite of many attempts to connect these two diseases, the conclusions reached have never satisfactorily expressed the suspicions entertained by the investigators that there existed an interdependence between this skin affection and the presence of glucose in the urine. F. Nagelschmidt gives some interesting data bearing on this question in the *Berliner klin. Wochenschrift* (Jan. 8, 1900), which he obtained from personally conducted experiments. He based his experiments and made them hinge upon the question as to whether patients affected with psoriasis are more prone to glycosuria than are healthy people or people affected with other skin diseases. The persons experimented upon received in the morning on an empty stomach 100 grams of grape-sugar dissolved in 0.5 of a liter of water. Then the urine passed immediately before this ingestion, as well as that passed hourly for three or four hours after, was examined carefully. During this period all other food and fluid were proscribed. The tests used in the examination were the Trommer, the Nylander, and the fermentation tests, together with the polariscope. Only those urines were declared positively as containing sugar which answered all of these tests. The experiments were carried out on 25 patients with psoriasis. The results were that 8 of these 25 (32 per cent.) suffered from alimentary glycosuria, whereas not one had a trace of sugar in the urine before the experiment. It can certainly not be said that this large percentage is a matter of chance only. At any rate, it offers a very interesting and instructive contribution to our knowledge of the matter in hand.

Tinnitus Aurium.—In a suggestive paper on this subject R. Panse of Dresden (*Archives of Otology*, vol. 28, Nos. 5-6) distinguishes two main groups of ear noises. (1) Low, dull ones, which preferably arise in the middle ear, like the resonance sound *C* of the ear drum after closure of the ear, or the muscle sound of yawning, or the vascular sounds heard during absolute quiet. (2) High, ringing ones, which arise from conduction into the labyrinth through the stapes, the fenestra rotunda, or the labyrinth watch. Panse discusses in particular a group of noises which do not interfere with hearing, the point of origin of which is surmised with difficulty. These he groups as: Conduction sounds; reflex sounds; tinnitus due to affections of the inner ear and nerve; blood sounds; sounds accompanying struma, atheroma, cardiac lesions, and anemia. His series of conclusions are as follows: (1) Almost all sounds should be designated by their pitch. (2) The pure conduction-sounds arise from the diminished outlet of sound, due to rigidity of the conducting apparatus. Inasmuch as the motility of the latter is required for hearing only low notes, its fixation is an obstacle to the outlet of these notes alone. Pure conduction-sounds are mainly placed between 16 and 256 vibrations. (3) The higher pitched sounds are due to processes in the inner ear. They may be produced (a) by reflex from the external meatus, middle ear, and many different parts of the body; (b) by changes in the inner ear or the nerve itself. In rare cases, however, low sounds may, perhaps, also originate in the middle ear. (4) Hearing of complex sounds like melodies, etc., is not prima-facie evidence of a cerebral affection. With reference to treatment, the rule is formulated not to perform any grave operations on the conducting apparatus when the sounds heard are high pitched, and especially not to attempt removal of the stapes.

Cystotomy or Litholapaxy.—Assendelft has had an extensive experience with stone in the bladder and reports the results of the treatment of 630 patients. In his opinion suprapubic cystotomy is the operation of choice for children up to the age of fifteen years, since litholapaxy in children requires the skill of the most expert specialist. He has been very successful with his operations in children, having a mortality of 1.8 per cent. in 327 operations on patients under twenty years of age. (*Archiv f. klin. Chirurgie*, vol. 60, p. 669.)

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, PH.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

SATURDAY, JANUARY 27, 1900.

ELECTROLYSIS IN THE EUSTACHIAN TUBE.

EVERY practitioner of experience knows how obstinate to treatment and how hopelessly progressive are the cases of increasing tinnitus aurium and advancing deafness that follow catarrhal conditions in the nasopharynx. Many of them can be improved by the use of the Politzer bag and by careful treatment of the nose and throat. And some cases that have proved obstinate to these measures yield to the use of the Eustachian catheter and direct inflation of the tympanum after dilatation of the strictures with bougies. A number of cases remain discouragingly obstinate to all treatment, however, and these patients have had to face, with advancing years, the prospect of hopelessly progressive deafness.

The method of electrolytic dilatation of strictures of the Eustachian tube, reinvented by Dr. Duel and described at a recent meeting of the Harvard Medical Society of New York City (see p. 150 of our present issue), seems to promise, in these cases, at least an amelioration of symptoms ordinarily pronounced hopeless. The results secured by this method in some fifty cases are such as to leave little doubt that a new and valuable bit of operative technic has been added to the armamentarium of otologists. The persistence of the results secured by the new method, however, has not been determined.

The disappointing failure of a similar electrical treatment for strictures of the urethra is too recent not to be at once recalled by the introduction of electrolysis into otology. But it must not be forgotten that the conditions in strictures of the Eustachian tube differ decidedly from those in the urethra. There is very little surrounding soft tissue to be deeply affected and made cicatricially contractile by the electrolytic treatment. And there is no passage of irritating fluids over the dilated parts to add further to the irritative contractility of scar tissue.

Present experience includes some cases in which amelioration has persisted, with but slight modifications easily relieved by periodic inflation, for nearly two years. This seems to justify the hope in some unpromising cases that a really helpful therapeutic method, comparatively simple of application, has been discovered.

THE TREATMENT OF ANEURISM.

THE physician who has a case of aneurism under treatment is apt to wonder at times if by treating his patient exclusively with drugs he is really giving him the best chance for the prolongation of life. Despite popular traditions to the contrary, many medical men share the very commendable sentiment of that grand old man of English medicine, Jonathan Hutchinson, who says that he looks back with most complacence on those cases in his medical career which he referred to others for treatment, because he thought they could do more for them than he could himself. Medical men would be only too glad, as a rule, to refer their cases of aneurism of the aorta to the surgeon, if there seemed to be a well-grounded hope for permanent relief by some operative procedure without a forbidding mortality. From the discussion of the subject before the Surgical Section of the New York Academy of Medicine (see p. ——), it appears that as the result of recent American efforts in this line there is something more than a gleam of hope for even the most serious of these cases.

The much-lauded gelatin injection treatment from which, after the favorable French accounts, so much was expected, has proved a failure in other countries. The latest device, however,

which consists in the wiring of aneurism followed by the passage of a mild electric current, has given excellent results. Dr. Stewart's pioneer achievements in this work have proved a source of encouragement to the profession throughout the country. The recent investigation in thoroughly scientific spirit of the technic of the operative procedures made at Johns Hopkins, brings out clearly all the possibilities for good that this method possesses in the treatment of large aneurisms. It will be a matter for sincere regret if after the reported results more of these patients are not given the chance for radical cure which the operation affords.

How tolerant of the presence of foreign bodies an aneurism may be is well shown by Dr. Wyeth's case, reported at the same meeting, in which a score of harelip pins were used instead of wire. The preconceived notion of the danger of the operation, which has so far served greatly to limit its use, is evidently exaggerated. The prospect of relief not only from actually annoying symptoms, but also from most of the subsequent dangers of the aneurism, are amply sufficient to justify the risk involved. In many cases the resultant clot is so firm and becomes in time so thoroughly organized that it does not seem too much to speak even of radical cure.

THE TREATMENT OF INOPERABLE SARCOMA.

Often the victims of sarcoma are at the very acme of apparent health and strength when attacked, and for modern medicine with all its vaunted progress to pronounce the cases hopeless has been a most mortifying experience. Extensive radical operations have done something during later years to remove this opprobrium, but much remains to be accomplished. In the midst of the general pessimism regarding cases in which recurrence has taken place, it is well to bear in mind that the surgeon's resources are not all exhausted after the use of the knife.

About a year ago we called attention to certain cases in this country and in England in which the sterilized toxins of erysipelas and the bacillus prodigiosus had undoubtedly been followed by permanent cure. In England especially the subject has attracted considerable attention during the last two years, and some extremely favorable reports have been made. In this country the pendulum of medical opinion, always going a little too far, has brought the profession to ignore too much the possibilities of this method. The striking case presented by Dr. Coley at the last meeting of the Section on Surgery of the New York Academy of Medicine (see p. 154 of this issue) illustrates forcibly how a hopeless prognosis may sometimes be utterly undone by applying this treatment. A cure lasting nearly three years of microscopically diagnosticated sarcoma, after a third recurrence, when metastases were already present, is indeed a surgical event deserving of attention.

The precise therapeutic mechanism of such cures remains a mystery. As in the cases in which severe infective processes lead to the complete disappearance of undoubted sarcoma, it is impossible to say what element is the curative factor or how the result is accomplished. A certain number of these cases reported by competent observers are met with constantly in medical literature. Dr. Wyeth gave at the same meeting of the Surgical Section the details of two such remarkable cures. The patients have remained well for eight and fifteen years respectively. We called attention some time ago to a similar case of Dr. Richardson's of Boston.

The subject is evidently worthy of most careful investigation. Meantime it must be borne in mind that inoperable cases of sarcoma cannot be pronounced hopeless, until the effect of bacterial toxins, or even of actual infection has been thoroughly tried.

ECHOES AND NEWS.

NEW YORK.

New Advertising Methods.—It is reported that Mrs. Minnie Maddern Fiske, the celebrated actress, has recently become a member of the New York State Antivivisection Society.

New Brooklyn Hospital.—Plans are preparing for the erection of a new building to replace the central section of the Long Island College Hospital. The new structure, which will cost about $150,000, will be four stories high and fire-proof.

Canned Foods.—A bill has just been introduced in the New York Legislature providing that the year in which a can designed as a receptacle for foodstuffs has been made shall be impressed upon its bottom and sides.

The Flower Hospital.—Through the generosity of the widow and the daughter of the late Roswell P. Flower, the Flower Hospital has recently been the recipient of $200,000. This was given on the condition that the name of the hospital should be perpetual.

Dr. Hammond Revered.—At a recent meeting of the Board of Directors of the New York

Post-Graduate Medical School resolutions of profound sorrow for the death of Dr. William A. Hammond were recorded, and expressions of respect for his memory were spread upon the minutes.

Medico-Legal Society's Dinner.—The Medico-Legal Society held its annual banquet and installation of officers on the evening of January 17th. Clark Bell, Esq., is the incoming president. The customary memorial to the English Government asking that clemency be extended to Mrs. Maybrick was sent.

A Correction.—In our last issue mention was made of the convalescence from typhoid fever of Drs. Pryor and Brown. By mistake Dr. Dillon Brown was mentioned instead of Dr. F. Tilden Brown. The former gentleman at last accounts was enjoying his usual excellent health. It is gratifying to know that Dr. Pryor and Dr. F. Tilden Brown are convalescing satisfactorily.

Bellevue Employees Poisoned.—Superintendent O'Rourke of Bellevue is investigating the strange illness of 180 of the hospital employees, who were poisoned at dinner on January 16th. The illness was mild in most of the cases, only one patient being obliged to take to his bed. Either some one poisoned the food, or accumulations of sediment in poorly washed cooking utensils generated a poison.

Health Report.—The Health Department presents the following report of contagious diseases for the week ending January 20, 1900: Measles, 777 cases and 28 deaths; diphtheria, 287 cases and 41 deaths; laryngeal diphtheria (croup), 10 cases and 11 deaths; scarlet fever, 245 cases and 13 deaths; smallpox, 1 case; chicken-pox, 33 cases; tuberculosis, 200 cases and 180 deaths; typhoid fever, 24 cases and 10 deaths; cerebro-spinal meningitis, 4 deaths.

The Bellevue Training School for Nurses.—Twenty-three young women were graduated from the Bellevue Hospital Training School on January 16th. This brings up the total number since the foundation of the school, twenty-two years ago, to 614. Graduates are working in every part of the world except Australia. Three are in South Africa, one is on the hospital ship "Maine," and another is organizing the first training school for nurses in Cuba.

Drug Clerks' Bill.—The Assembly Committee on Labor and Industries gave a hearing on Tuesday, January 23d, on Assemblyman Maher's bill providing for shorter hours for drug clerks in New York City. Last year Mr. Maher had the same bill before the Legislature, and it passed, but at the request of the drug clerks, who came here en masse to protest against it, the Governor refused to sign the bill. The bill now provides that they shall not work more than 168 hours in two weeks.

Smallpox Patient Abroad.—William Brown, a negro from Virginia, after lodging three nights in a tenement went to Bellevue feeling ill. This was on January 22nd. After sitting in the reception room of the out-patient department for about an hour, he was told that he had a trivial illness and was sent to the city lodging-house in Twenty-third street and First avenue. At 8 P. M. of the same day he returned to Bellevue and sat another hour in the reception-room, when his illness was diagnosticated as smallpox. Wholesale vaccination and disinfection followed.

Cigarette-Smoking by Minors.—Although it seems to have been scientifically proved that cigarette-smoking *per se* when indulged in to a reasonable extent by adults is not injurious, it has been demonstrated with equal certainty that when practised to an excess, or at too early an age, it is destructive to health. Complaint has been made that the smoking-cars on the Brooklyn elevated road are frequented by boys under the age of sixteen years smoking cigarettes or pipes. The other passengers frown on the practise and sometimes the guard interferes, but there seems to be no systematic attempt to enforce the section of the Penal Code relating to children in this matter.

Charity Inspection.—To supplement the inspection work of the State Board of Charities, occasioned by the recent decision of the Supreme Court that the Gerry Society did not come under the provisions of the law, a resolution has been introduced at Albany providing for the appointment of five members of the Assembly to investigate the affairs of the Society for the Prevention of Cruelty to Children, and report to the Legislature before adjournment. The preamble to this resolution recites that the Society receives $30,000 annually from the city of New York, and that no authentic information had been received as to the financial standing of the institution.

Medical Ethics Observed.—The secular press has during the past week given great prominence to an operation performed at the Seney Hospital in Brooklyn in which the lining membrane of the shell of a hen's egg was used as a skin graft for covering a large granulating surface. This is the first time in the history of surgery in the United States that the lining membrane of an egg-shell has been usd for grafting purposes. The operation proved successful. It is especially noticeable in all these reports that the name of the operating surgeon did not appear. This was due to the fact that the surgeon insisted that the reporters should be given no information regarding the case except on the explicit understanding that his name should not appear. The reporters surprisingly kept their part of the agreement. There is no objection to the profession knowing, however, that this unique surgeon of these advertising times is Dr. George R. Fowler of Brooklyn, Professor of Surgery at the New York Polyclinic.

Doctor's Diploma for Sale.—Supt. O'Rourke of Bellevue Hospital recently made public a letter

which came from Detroit, addressed to "The Superintendent of Bellevue Hospital." It informs him that a graduate of the University Medical College has fallen into poverty and would like to sell his diploma. The writer says: "The only purchaser for such a thing, of course, would be some student who had failed to pass his examinations, or some man who, for business reasons, wanted a medical diploma and could not get one in the ordinary way; or some student who had gone part of his time to college and had to quit for some reason. As to the price, $500 is less than half what it cost its owner to get it. Of course, it is worth more than that, particularly to a man who has failed and will have to give up altogether unless he can go home with a diploma." And this is added: "Fifty to $100 that some one, yourself if you care to try for it, can make by selling it for my friend. If you don't care for it, can you give me the name of some one who would care to work up a customer for it? It occurs to me that some of those South American fellows who are always about the University and Bellevue might be a good customer for it." The letter was signed "H. J. Buttonbook, care General Delivery, Detroit, Mich."

PHILADELPHIA.

Health Reports.—Deaths in the city for the week ending January 20th were 525, an increase of 21 over those of last week and a decrease of 61 from the corresponding week of last year. Contagious diseases: Diphtheria, 145 cases and 26 deaths; scarlet fever, 102 cases and 4 deaths; enteric fever, 35 cases and 8 deaths.

County Medical Society.—The Philadelphia County Medical Society has elected the following officers for the present year: President, Dr. John H. Musser; first vice-president, Dr. G. E. Shoemaker; second vice-president, Dr. Francis Perkins; secretary, Dr. E. R. Kirby; assistant secretary, Dr. W. S. Wray; treasurer, Dr. C. L. Bower; censor, Dr. T. H. Fenton.

Jefferson College.—A decided innovation in medical clinics has been introduced by Professor Hobart A. Hare in his course at the hospital. Lantern slides illustrative and explanatory of the cases shown are thrown upon a screen by an assistant. Tabulated charts, as well as photographs, are included. The scheme is heartily endorsed by the students.

Hospital for Contagious Diseases.—A pay hospital for contagious diseases has recently been chartered and the incorporators have elected officers for the year, the president being Hon. William N. Ashman. Efforts to secure a building are being made, the Women's Branch of the Board having announced a bazaar at Hotel Walton February 7th in aid of the movement.

Pediatric Society.—At a meeting held January 9th Dr. Griffith stated his disagreement with writers who associate miliaria with severe rash in scarlet fever. Four cases were reported in which miliary eruption was present with only ordinary intensity of the rash. He believes that there is no relation between feeling and the miliary eruption; that the latter is due to a peculiarity of the skin, and that its appearance is no indication of a severe attack of scarlet fever.

Consumptive Poor.—The treasurer of the Free Hospital for Consumptives reports that an expenditure of $7,000 was made in caring for the consumptive poor during the year just closed. This hospital association has not yet obtained a special hospital for these patients, but efforts are being made to establish one. Meanwhile the association endeavors not only to alleviate the suffering from consumption itself but also that entailed by the abject poverty which inability to work brings to many unfortunates.

School Hygiene.—The Committee on Hygiene of the Board of Education has been revivified and announces its intention of exercising a careful supervision of the schools. Plans for new buildings and improvement of old ones are subject to their approval. The necessity of the Board employing an inspector with a thorough technical training is to be emphasized and is a move in the right direction. The Women's Sanitary League has presented a petition asking that there be introduced in the schools instruction regarding the dangers arising from expectoration.

Water Filtration.—The season of freshets has begun and the water supply of Philadelphia, always bad, is periodically an indescribable mixture. However, as our great and only Munyon says, "There is hope." The Finance Committee of City Councils has reported favorably on the bill authorizing a $12,000,000 loan for filtration purposes and the bill will undoubtedly become a law. Experts have already submitted a report on various methods and purer water is assured—for posterity, at least. In the meanwhile the long-suffering Philadelphian will continue to take his *aqua pura* fried on one side or turned, as his fancy may dictate.

Antinomycosis.—At a recent meeting of the Pathological Society Dr. Simon Flexner exhibited the lungs taken from a woman dying of the above disease. She had a cough for many months, pain in the chest, particularly the right side, followed by a swelling which broke down and left a sinus. Examination of the pus from this sinus showed the presence of actinomyces grains. The main lesions of the lungs were in the lower lobes, the consolidated areas extending nearly through the organ. In addition to the principal foci, fragments of mycelial threads were scattered throughout the lungs. At first these were thought to be due to some other organism but none was found and the actinomyces is believed to have caused this diffuse appearance as well as the foci.

Sweat Shops.—The factory inspectors of the city are determined to put a stop to the making of clothing in the slum tenements where contagious diseases are known to exist and the sweat-

shop law is being rigidly enforced. Last week a house in a locality where diphtheria and scarlet fever were known to exist was visited and over 200 pairs of trousers found there were condemned and sent to the Municipal Hospital where they were destroyed. The owner of these goods made a vigorous protest, as he was about to send them away to various stores. The house contained about 25 people and among these were found two cases of diphtheria and one of scarlet fever. Other manufacturers are being watched and violators of the law will be prosecuted.

Pennsylvania Hospital Clinics.—Dr. J. M. Da Costa recently exhibited a case of spastic paraplegia of congenital origin, it being the first case of that rare variety which this experienced clinician has seen. The history of the patient, a boy eighteen years of age, was carefully investigated and absolutely nothing pointing to cerebral involvement after birth could be elicited. This, together with the fact that the patient's sister had the same disease, was believed to make the case a perfectly clear one of the congenital variety.

Dr. A. V. Meigs believes that the bacteriological diagnoses made in the laboratory of the Board of Health from throat cultures sent them by physicians are often contrary to clinical facts. For this reason the posters put upon houses where contagious diseases are supposed to exist may be the source of needless annoyance and damage to many families. In his private practise he does not send cultures to the Board of Health, preferring to keep his patients under his own control. He advises that in a case presenting difficulty in diagnosis a culture be sent to a reliable private laboratory for examination. This gives the benefit of a bacteriological test while the physician still controls the case, can make his own diagnosis, and can say when his patient is well without being interfered with.

Examination Frauds.—The investigation by the State Medical Examiners regarding the fraudulent obtaining of questions by applicants for license at the meeting of the Board in this city in July, 1899, is still under way. The State printer, his foremen, and employees have appeared before the Board and the unsavory affair is to be thoroughly probed. The questions used at the meeting of the Board in December were read to the candidates instead of being printed, and the fact that of the 83 candidates from regular schools 35 failed is considered significant.

Philadelphia physicians denounce the action of Gov. Stone in failing to reappoint to the Board Drs. J. K. Weaver of Norristown and S. W. Latta of Philadelphia, whose terms recently expired. These men have been among the foremost in efforts to raise the standard of the medical profession and were especially active in advocating the strict interpretation of the four-year law and in pushing the investigation of the rumored examination frauds. No objection to their successors is raised, as they are men of unquestioned ability, but it is felt that the retirement of these two men at this critical time is a serious loss to the Board. Politics of the inimitable Quay brand is thought to be at the bottom of the change. However this may be, at least one of the new members has pledged his hearty support in furthering the investigation now being conducted. The finding of the Board is being anxiously awaited.

CHICAGO.

Meeting of State Board of Health.—The State Board of Health held its quarterly examinations at the Great Northern Hotel, January 16th. On the first day there were 43 candidates who took the examination for degrees; 18 for degrees in osteopathy, 11 for physicians, and 14 for midwives.

Emergency Hospitals.—A delegation of women physicians visited President Irwin of the County Board, urging the establishment of an emergency hospital in the First Ward, and explained to him that they believed such a hospital should be provided in every ward. The plan meets with the approval of Mr. Irwin, but he thought the matter should be taken up by the City of Chicago and not by Cook County. He thought the County was in no condition financially to add to its burdens.

Death of Dr. Hoadley.—Dr. Albert E. Hoadley, who had practised medicine in Chicago for twenty-eight years, died January 16th, from fatty degeneration of the heart. He was born at Chenango Forks, N. Y., on November 19, 1847. He graduated from the Chicago Medical College in 1872, and he was professor of orthopedics and clinical surgery in the College of Physicians and Surgeons, a member of the local societies, and likewise a member of the American Medical and American Orthopedic Associations.

Medical Inspection.—The medical inspection of schools inaugurated by the Board of Education resulted in the examination of 3054 pupils last week, of whom 323 were excluded from schools because of the danger of infecting other pupils. The Commissioner of Health gives his opinion that this protection to the school children must result in the prevention of much sickness and suffering and will save the lives of many who otherwise might die from contagious diseases.

Wesley Hospital.—The new $250,000 Wesley Hospital, for the building of which $150,000 has already been subscribed, will be under the management of the present building committee and the Deaconess Society. The medical staff will be composed of both regulars and homeopaths.

Diploma Mills.—The Secretary of the Illinois State Board of Health is reported as saying that academical Europeans cannot be persuaded that in Chicago degrees are not turned out by the diploma mills "as fast as they kill hogs." If the

degrees were only as genuine as the hogs, no one could complain.

Estimates for Health Department.—Health Commissioner Reynolds has asked for $256,894 to run his department during the year. The largest amount requested is $60,034 for maintenance, supplies and contingent expenses. This item includes the Isolation Hospital, public vaccination, antitoxin treatment, stationery, printing, disinfection, chemicals, and laboratory supplies, transportation expenses for disinfectors and inspectors, as well as $4,200 to complete and $7,500 for the extension of the Robert A. Waller bath. The chief increases asked by the Health Department are in the contagious disease division, where the force of medical inspectors and disinfectors has been increased from ten to twenty, an addition of $19,000.

Vital Statistics.—Deaths for the week ended January 13th were seven fewer than the week preceding and forty-six less than in the corresponding week of 1899, according to to-day's weekly bulletin of the health department. Pneumonia and bronchitis together caused 129 of these deaths, or slightly more than 23 per cent. of the total. This is a small reduction compared with the preceding week, but a marked reduction compared with the corresponding week of 1899, when pneumonia was responsible for 127 deaths and bronchitis 31, a total of 158, or 28 per cent. of the total mortality. For the corresponding period of 1899, influenza was responsible for thirteen deaths, while for the week just closed there was but one death attributable to this cause. During the week there were five fewer deaths from diphtheria than in the preceding week, and an increase of one from scarlet fever. The mortality from both these diseases is still excessive.

First Voyage Down the Drainage Canal.—A twenty-eight mile trip from Chicago to Lockport, over the drainage canal, in a row-boat, by a reporter of *The Times-Herald* staff a day or two since revealed that beyond Kedzie Avenue, in this city, to Lockport, the water is practically free from offensive odor; that foul masses of city sewage are not flowing down the channel in such form as to menace health or life anywhere; that the sewage in the stream is in saturation, gives ample evidence of disintegration and aeration, and that water discoloration in the main channel is due less to the presence of sewage than to seepage along the earth sections. No great surface indication of the presence of poisonous filth could be found. The current moves at a rate of between one mile and a quarter and a mile and a half an hour, and the water is rapidly clearing. The channel is easily navigable, the present water-depth being twenty-five feet, and there is no offense to nostril or eye in any portion of the trip.

GENERAL.

The "Maine."—The American hospital ship "Maine," which left England December 23rd, arrived at Cape Town January 21st and proceeded to Durban January 25th. All were reported well and everything satisfactory.

A Medical Journal Suspends.—The *South African Medical Journal*, published at Cape Town, and many of whose subscribers reside in the Orange Free State, Natal and Transvaal, announced with its December issue that it would discontinue publication for six months.

Pure Food and Drug Congress.—The third annual meeting of this national assemblage will be held at Washington, D. C., March 7 and 8, 1900. This national organization is making strenuous efforts to have the National Pure Food bill passed by Congress.

Eddyites Indicted.—The Grand Jury of Council Bluffs, Ia., recently returned true bills of indictment against two followers of Mrs. Eddy, on the charge of being criminally responsible for the death of a young woman under their care who was sick from appendicitis.

Typhoid in Trenton.—There is a quite unusual epidemic of typhoid fever in the city of Trenton and its suburbs. The number of cases has grown from the average of twelve in a week to forty. The outbreak is generally attributed to the city's new reservoir.

Obituary.—Dr. Abram H. Wittmer, first assistant physician at the Government Hospital for the Insane at Washington, died on January 18th, in his fifty-fifth year. He was connected with the Government Hospital for over twenty years, and was a member of a number of prominent medical societies.

Vaccination in Connecticut.—During 1899 there were, according to the report of the State Board of Health, but three cases of smallpox in Connecticut. This immunity is attributed to the thorough manner in which vaccination has been done in the public schools, and to the wise and effective legislation which permits the exclusion of unvaccinated pupils from the schools.

Another Gift.—Mr. James Stillman of New York City, who recently gave $50,000 to Harvard University for the purpose of establishing a hospital and infirmary for sick students, has doubled the amount. The advance in the price of real estate and building materials has necessitated this additional sum in order that the original plans might be carried out.

Cuban Prisons.—MajorRuncie, who has been officially investigating the conditions of the prisons in Cuba, describes the women's prison as a den of filth and iniquity; he did not find a cot, a blanket, or a female attendant in the prison, where several hundred women are confined. The sanitary conditions are almost indescribable. This state of affairs is the worst arraignment of Spanish mismanagement that has yet been discovered.

Mules Vaccinated.—The British Admiralty has issued a decree that the American mule must

be vaccinated before he can enlist in the British army service in South Africa. This action was due to the fact that a large number of mules have died of glanders since their arrival on African soil. In the future all mules designed for South Africa will be inoculated with antiglanders serum or virus in this country before embarkation.

Dr. Conan Doyle.—Our professional brother across the water has experienced a change of heart since he presided at a peace meeting some eight months ago, and now declares that he has seen more positive virtue in Great Britain during the last few months than he had seen during the previous forty years. He regards President Kruger as a benefactor of the British Empire, and suggests that a monument be erected to him as large as St. Paul's cathedral, putting Oom Paul under it and inscribing upon it: "To the memory of the man who federated the British Empire."

The Plague.—The steamer "Doric" which arrived January 19th at San Francisco from Asiatic ports, *via* Honolulu, reports a fresh outburst of the plague, six deaths having occurred within a week. This brings the total number of deaths up to 18. It is understood that there are 26 cases in the hands of the health authorities. Surgeon-General Sternberg has received a cable from Major Blair Taylor, chief surgeon of the United States Military Hospital at Honolulu, reporting three additional cases and one death. He believes that the disease will be eradicated by the energetic measures used. The Honolulu Board of Health has $270,000 at its disposal, and has destroyed by fire the houses of the infected district. Reports from Buenos Ayres, Argentine Republic, January 24, announce that the plague has invaded Rosario, but that a vigorous cordon has been established.—The epidemic in India continues to spread among the famine-stricken populace but no new centers of invasion have been reported.

Dr. Howard A. Kelly Snake-bitten.—In the course of a lecture, on January 22nd, Professor Howard A. Kelly of Johns Hopkins was bitten by a rattlesnake, which he was exhibiting. With great coolness he sucked the wound for a minute, told his horrified audience there was no occasion to be disturbed, and continued to talk for over an hour. There was very little poisoning. The biting occurred while the doctor was returning the rattler to its cotton sack. As soon as he removed his hand the snake struck, sending its fangs through the sack and into the flesh. On this account the bite was not so virulent as it might have been. Dr. Kelly has been making a study of snakes for a number of years and he anticipates publishing a work on the reptiles of North America. He has a large collection, procured in various sections of the country, including the rarest specimens known to naturalists.

NOTABLE BOOKS.

"DIE KRANKHEITEN DER LEBER" (*DISEASE OF THE LIVER*).[1]

"SYSTEM DER BACTERIEN."[2]

DISEASES of the gall-tracts have attracted so much attention recently that this contribution to our knowledge of liver diseases cannot fail to be of more than ordinary interest. It has been claimed that most of the diseases of the liver belonged rather to the surgeon than to the medical man. We need only recall the fact that for atrophic cirrhosis, especially when complicated by ascites the most successful treatment is suture of the liver to the belly wall with the consequent formation of adhesions, the development of a collateral circulation, and the relief of the obstruction in the circulation. Of late, gallstones have been claimed to be from the beginning a surgical and not a medical affection. Abscess of the liver is now opened as soon as diagnosticated. No palliative treatment is considered justified for a moment and even the trocar methods of emptying the purulent collection are finding less and less favor.

It is interesting then to find a recent book in which the medical aspect of liver disease is considered and in which the serious problems connected with the diagnosis of affections of the liver are put as clearly as is possible with our present knowledge of the pathology of that organ. The extent to which our knowledge of liver disease has broadened in this last half century is very strikingly displayed by one fact. The old morbus regius, or jaundice, which had fifty years ago practically an independent existence, is now considered a symptom of a very large number of different affections. Psychic icterus is a thoroughly established etiological division of the disease which a few years ago was very little considered. Icterus menstrualis, a jaundice occurring during the menstrual period and without any special pathological change to account for it, is another interesting type of the disease. A form of icterus that has received a good deal of attention during recent years is that following the ingestion of various poisons. It has been noted that even such familiar drugs as ether, chloroform, chloral hydrate and certain arsenical preparations may furnish occasion for the development of jaundice.

The chapter on cholelithiasis, written by Hoppe-Seyler, is deserving of special attention because of the present widespread interest in the whole subject of gall-stones and their treatment. Much more importance is placed on the wearing of corsets as a cause for gall-stones than is usual. In addition to the corset, there are in women two

[1] "Die Krankheiten der Leber" (Diseases of the Liver). By Professors Quincke and Hoppe-Seyler of the University of Keil. Vol. XVIII, part I., Specielle Pathologie und Therapie; edited by Professor Nothnagel of Vienna. Vienna: Alfred Hoelder, 1899.

[2] "System der Bakterien." Handbuch der Morphologie, Entwickelungsgeschichte und Systematik der Bakterien. Von W. Migula. Gustav Fisher, Jena. 1900. Zweiter Band.

other causes that are supposed to lead to gall-stones, *viz.*, pregnancy and an indoor life.

For those who delight in statistics, the number of gall-stones that have been found in certain cases is of interest. In one of the gall-bladders of the Otto collection 7802 gall-stones were counted. Naunyn found in one gall-bladder over 5000 gall-stones, and Friedrich Hoffman reports a case in which 3642 were found. It is not an unusual thing to find gall-stones of different composition in the same gall-bladder. Hein who investigated 632 cases, found 28 instances in which the stones were of unlike composition.

Syphilitic hepatitis is considered here to be a much more important affection than is usual, and the authors write that cirrhosis and syphilitic disease of the liver are often confused in diagnosis. Sometimes the resemblance between a multiple gummatous cirrhosis and an ordinary cirrhosis of the liver is very striking. Where remissions occur, especially where the ascites comes and goes irregularly, and where the disease runs a course of several years, the cirrhosis is usually syphilitic. These are the cases of so-called cirrhosis of the liver which recover.

Syphilitic affections of the liver, as is well known, occur not infrequently in very young children as the result of heredity. Clinically this condition is often missed, yet the diagnosis of the affections is not at all difficult, since the liver in young children can be readily palpated and other liver affections are very rare. Many of the digestive disturbances in young children with syphilitic heredity are due to affection of the liver. Many of the cases of marasmus of doubtful origin are to be attributed to syphilitic hepatitis.

According to the authors, a true biliary cirrhosis, due to the destruction of the liver-cells by the irritative presence of bile and the overgrowth of the connective tissue, is possible but is very infrequent. As to the other form of so-called biliary cirrhosis, they say very properly that it is a misnomer and that it should properly be called cirrhosis cholangica. The sclerotic condition is not due to the biliary secretion, but only begins in the tissues of bile-ducts.

Two years have gone by since Migula wrote the first volume of his work on bacteriology. It was then seen that an entirely new influence had entered this field. Hitherto, with but few notable exceptions, the bacteriological domains had been given over almost entirely to the student of the medical sciences. Physicians, surgeons, and hygienists were eager in the work of new discoveries in this line and it was not until Migula first published in Engler and Prantl's "Die Naturliche Pflanzenfamilien," a chapter on the lower fungi, treating of the bacteria, that the strictly botanical hand made itself apparent. This second volume serves to accentuate this strictly systematic mode of treatment and also, in part, crystallizes a number of hazy conceptions pertaining to the relationships of the different genera treated.

As far as the medical world is concerned, the old grouping into pathogenic and non-pathogenic organisms, is sufficient for all practical purposes, but the student of natural science, botanist or zoologist, in one field of research at least, is impelled, by the well-known mania for classification, to arrange his objects of study in some logical order. In this volume of 1080 pages, with eighteen tables and thirty-five figures in the text, Migula has given a comprehensive botanical classification of all the then described species and has tried to bring some order out of the chaos of bacterial nomenclature.

His classification follows the lines already laid down in "Die Naturliche Pflanzenfamilien," and is here given in an abridged form. The bacteria are divided into two large groups, the Eubacteria and the Thiobacteria; the former are characterized as bacteria containing no central body (nucleus ?), sulphur, nor bacteria purple; colorless or lightly tinged, sometimes green like chlorophyl; the latter as bacteria containing no central body, but possessing sulphur and bacteriopurpurin, colored red, or pink or violet, never green. The families are the (1) Coccaceal, with the genera, Streptococcus, Micrococcus, in which is included the various forms of Diplococcus and Staphylococcus, Sarcina, Planococcus and Planosarcina. (2) Bacteriaceal, containing the genera Bacterium, which is raised to a generic rank, Bacillus and Pseudomonas. The separation of these three genera is based on the flagella. The species of Bacterium do not posses flagella and are non-motile, those of Bacillus are motile and posses numerous flagella, covering the body of the bacteria; while the forms of Pseudomonas are motile, but the flagella are collected at the ends. (3) Spirillaceal, made up of the genera, Spirosoma, Microspira, Spirillum and Spirochaeta and (4) Chlamydobacteriaceal. In this family the bacteria are rod-like and elongated into threads, which threads are surrounded by a sheath. Reproduction is effected by means of spores or conidia which may be motile or non-motile. The genera and species of this family are few and are imperfectly known. Chlamydothrix, Crenothrix, Phragmidiothrix and Sphaerotilus are the genera.

The Thiobacteria represent but few forms, when compared with the Eubacteria, occupying but ten pages of the 1050 devoted to the study of the bacteria. This genera and species are unimportant from the medical point of view. Most of the species are inhabitants of salt and fresh waters.

From the above brief discussion it might appear that this work would prove of interest to biological students alone. This is far from the truth and it should be known to every working bacteriologist as it may be said to be the first serious effort made to bring the vast mass of known bacteria into some sort of systematic order.

CORRESPONDENCE

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, January 13, 1900.

DEATH OF SIR JAMES PAGET—THE "BOY PROFESSOR"—EARLY SUCCESSES—HUNTERIAN ORATION—FUNERAL IN WESTMINSTER ABBEY—BRITISH PHARMACOPEIA BEFORE THE COURTS—CHRISTENING AS A THERAPEUTIC AGENCY—SEATS FOR SHOP-WOMEN—SPREAD AND FATALITY OF THE INFLUENZA IN LONDON.

Widespread is the grief of the profession over the passing, with the last days of the old year, of one of the foremost surviving figures in English medicine. Sir James Paget had been for several years completely withdrawn from both the practise and the active interests of the profession, having been confined to his house, indeed, for the most part to his room, by the weaknesses incident to old age, but his influence and his memory were still fresh and powerful, his sick-room was a center of reverent sympathy, and the news of his departure comes with the shock of bereavement. To enumerate his triumphs and matchless services to surgery would be superfluous, the name of Paget, coupled with the classic "Lectures upon Surgical Pathology," is a household word in the profession and the work a classic and an authority still in spite of the half century which has elapsed since its appearance. And it was written by a young man of barely thirty-three, against whose appointment to deliver the lecture-courses of which it is made up, the protest was raised of "setting a boy to teach us surgery." The lectures established his fame at once and from this time on his career was one steady procession of honors. Warden and surgeon to St. Bartholemew's Hospital, where his great teaching-work was done, Fellow of the Royal Society, President of the College of Surgeons, Baronet, Surgeon to the Queen and Prince of Wales, these are a few of the milestones of his progress. He was even more beloved than famous. Gentle, modest, courteous to all, in his successes, as in his early struggles, he was one of Nature's noblemen and his baronetcy was literally "but the guinea's stamp." Seldom has a more brilliant audience assembled to do honor to any member of our profession than that which listened spellbound to the eloquence of his Hunterian Oration in 1877. From the Prince of Wales to Professor Huxley, from Mr. Gladstone to the Marquis of Ripon, leaders in every field of activity were present. Although half a generation has passed since then and many of that brilliant company have joined the majority meanwhile, yet so enduring was his fame that his funeral services in Westminster Abbey yesterday were attended by hundreds from all walks of life, who strove to do him honor Wreaths were sent by the Queen and the Prince and Princess of Wales, who were also personally represented, and the pall-bearers were headed by Lord Lister and Sir Michael Foster. Seldom does a member of our retiring and little-celebrated profession attain such widespread fame.

That memorable document, the British Pharmacopeia, has been before the courts this week and on the whole came out the worse for the ordeal. A certain druggist was summoned by a zealous medical officer of health for selling a compound rhubarb powder which on analysis was found not to conform to the B. P. standard, containing only 30 per cent. of magnesia, instead of the required 60 per cent. This certainly seems a harmless enough variation and one can hardly wonder that the magistrate refused to convict, but his grounds went further than this. He declared that the British Pharmacopeia had no legal status whatever as a standard of genuineness in drugs or compounds, and that unless a drug was called or purported to be made according to the B. P. standard, it could not be held to or judged by that standard. This is unquestionably sound law and good sense, especially in view of the trivial nature of the departure from the standard formula and yet it certainly would be desirable to in some way insure that staple and commonly used compounds, such as the familiar rhubarb, licorice and opium "compounds," whose names in themselves mean little that is definite, should be held to a rather rigid standard of uniformity. And this would naturally and most conveniently be that of the British Pharmacopeia.

A strange and ghastly instance of the power of superstition even in these later days was furnished by an inquest held by Mr. Braxton Hicks this week upon the body of a baby seventeen days old. The autopsy showed death to be due to bronchopneumonia. The mother gave the extraordinary evidence that the child was ill on Wednesday, worse on Thursday, *so on Friday she took it to church to be christened!* Saturday morning it died. And this in the rawest, foggiest month of the year and an unusually bad month at that. Mr. Hicks remarked that he had had several similar cases before him during the past few years, children seriously ill, taken to be christened and dying in consequence. The explanation, of course, is simple. There is a firm belief, actually taught by the clergy until comparatively recent times, that the souls of infants dying unbaptised hover forever between heaven and hell; so that devout parents would risk much for their infants in this life to ensure their welfare in the next world, even at the hazard of hastening their departure thither, and the poor little victim is christened for its own funeral.

The new Act compelling merchants to provide seats for their shop-girls and women employees, which came into operation with the New Year is cordially hailed by medical men. Curiously enough its original introducer, Sir John Lubbock, was raised to the Peerage on the same day. The Act has had excellent effects already, as many of the better class of shopkeepers have pro-

vided their stores with seats for some time past, some since immediately after its passage and without waiting for the date when it should become actual law. The requirement is one seat for every three assistants, and ought to result in the saving of much suffering and even permanent disabilities and displacements.

Much uneasiness is felt over the continued spread of the influenza and fears are expressed that a serious epidemic like those of 1891 and 1893 is in prospect; indeed, the record already is higher than any previous November and December except in those two years. *One hundred and ninety-three* deaths attributed to influenza in one week is certainly enough to alarm us, especially now that "influenza" as a formal cause of death is handled so much more cautiously than in earlier years. This is evidenced by the huge death-rate from respiratory diseases, nearly 600 above the corrected average for the week for the past ten years, chiefly from bronchitis and pneumonia. So far the pest itself, although very widely spread, is of rather a mild type and presents no new features; indeed, it had so many varied ones before that there seem none to present.

OUT-OF-DOOR TREATMENT OF CONSUMPTION — PROGNOSIS OF APPENDICITIS—SURGICAL TREATMENT OF ASCITES—SENILE TUBERCULOSIS—TWELVE CONSECUTIVE CASES OF PERFORATED GASTRIC ULCER.

In a discussion on the out-of-door treatment of consumption at a meeting of the Royal Medical and Chirurgical Society, November 28th, Heron called attention to the almost universal approval of this method. It is certainly very unusual that any form of treatment should be so widely advocated for two years without a single dissenting voice in the profession being raised. A life out-of-doors, either of amusement or occupation, plenty of wholesome food, and a bedroom arranged so that the patient is practically sleeping out-of-doors without being subjected to drafts, is a day's program that any man of common sense can follow out without going to a sanatorium. The speaker mentioned several instances in which patients have been able to earn their livelihood near home by doing the work of a gardener, land agent, pedlar, etc., although these occupations were quite new to them at the start. Such employment, or, if circumstances permit, the playing of fives, cricket, golf, or some other game, or skating or rowing, is far better for the patient than merely walking up an incline, and then walking down again. Many patients are annoyed by being required to make daily visits to their doctor. If all is going well, there is no necessity that a patient with incipient tuberculosis should see his physician oftener than once in ten days.

J. E. Pollock said that the mortality from phthisis in 1838 was 38 per 1000 of persons living, while in 1892 it was 14 per 1000. The health of the whole population has improved, and some diseases have been extinguished, not on account of any special treatment, but because of better sanitation, better dwelling and increased comforts of the whole people. In the Brompton Hospital for Consumptives, the results will compare favorably with those obtained on the Continent or elsewhere. Very little medicine is given, but the rooms are airy and well ventilated, for an abundance of pure air is supplied, which is heated by passing over pipes. The temperature is kept at 60-63° F., winter and summer, and the patients are encouraged to stay out of doors as much as possible.

F. G. D. Drewitt called attention to the fact that in the zoological gardens granivorous birds die in large numbers from tuberculosis, while meat-eating and fish-eating birds die much less frequently from that disease. Carnivora rarely die from tubercle, but caged animals do, whatever their dietary. The conclusions are obvious that human beings close-housed and fed largely upon starches will be especially susceptible to the ravages of consumption.

P. Weber agreed with the last speaker as to the value of proteid food for the consumptive. Men who have a tendency to gout, and who take large quantities of meat, are less likely to suffer from consumption than poorer people who cannot afford an excessive meat diet. Experiment showed that if a certain number of dogs are infected with tubercle and then fed some on meat and some on farinaceous food, those fed on meat are less prone to develop tubercle than the others.

In closing the discussion, K. Fowler spoke of the great difficulty in getting medical men and patients to realize the length of time required to bring about an obsolete condition of the lesions. The word cure should never be used, or only after finding out what meaning the patient attaches to it. It is seldom true that all physical signs disappear, unless reference is had to adventitious signs alone. These were as a rule absent from arrested lesions, although when emphysematous changes have taken place around a fibroid lesion, a few bubbling râles may remain.

At the meeting of December 12th, S. Martin said that the slow growth of tuberculous lesions, the prolonged vitality of tubercle bacilli in animal tissue, and the very problematical formation of antitoxic substances in the patient infected by tuberculosis, are in strong contrast to some of the acute infectious diseases. Mankind must be considered relatively immune to tuberculosis. The bacillus certainly tends to become quiescent. One of the most important questions in connection with the treatment of tuberculosis is that of secondary infection, either by the streptococcus, or by the bacillus of influenza, or in children by the agents of acute infectious diseases. To prevent secondary infection is one of the objects of treatment by fresh air, and in sanitary surroundings.

The dissemination of knowledge concerning tuberculosis has done good in several ways. It has led to the taking of measures for the destruction of the sputum, and the disposal of clothing soiled by the patient. It has also led to the protection of the alimentary tract by greater attention to the health of cattle, and by the boiling of suspected milk. Physicians have also learned that a tuberculous patient who has fever must be kept at rest like any other febrile patient; and that a patient ill with tuberculosis must be intelligently treated, and not sent on long voyages in a haphazard way, in the hope that change of climate may effect a cure. An excess of food may be of advantage to repair waste of tissues, but in this respect judicious feeding rather than over-feeding should be the rule. A change in the life of the patient, even without a change of locality, may be the turning point toward recovery. In the houses of the well-to-do this can be accomplished without sending the patient to a sanatorium.

At the Medical Society, November 27th, Caley opened a most interesting discussion of the prognosis of appendicitis. In the medical and surgical wards of St. Mary's Hospital, 200 consecutive cases of appendicitis were treated. There were 99 cases of simple appendicitis and perityphlitis—that is, cases in which the peritonitis was localized and non-suppurative. All of these patients recovered. In 31 cases there was localized suppuration, and of this class 2 patients died. In 23 cases there was general peritonitis, and of this class 20 patients died, many of them being, it is true, in a hopeless condition when received into the hospital. There were 42 cases of chronic and relapsing appendicitis, in 37 of which the appendix was removed. All of the patients of this class recovered. For prognostic purposes the lesions of the appendix may be considered as severe and mild. The severe lesions are perforation, gangrene, ulceration, and sometimes concretion and suppuration within the appendix itself. Most of the fatal cases are associated with perforation and gangrene. Mild lesions are simple inflammation, whether acute or chronic; stenosis or obliteration of the lumen with or without cystic dilatation of its distal portion; some forms of concretion; superficial ulceration; kinking; volvulus, or extensive adhesions. Most chronic cases present these symptoms, which are mild as far as the probability of an extension of the peritonitis is concerned. Persistent severe pain or vomiting, or a sudden return of pain or vomiting after an interval of quiet, are symptoms which almost always indicate a severe case. The same may be said of a pulse persistently above 120, or an initial collapse, even if it is soon succeeded by a more comfortable period. The prognosis for recurrence has been variously given at from 30 to 47 per cent. In Caley's cases it was 31 per cent. Usually the second attack comes within a year, almost certainly, if at all, within two years. There will surely be a recurrence if there is pesistent pain and local thickening.

Berry spoke against a hasty incision in acute cases. In 24 acute cases, treatment was by free incision. Five patients recovered and 19 died. In 21 strictly comparable cases the expectant method of treatment was employed, to be followed by limited incision. Nineteen patients recovered and 2 died. Under the charge of another surgeon, 9 similar cases were treated by free incision. Of these patients 7 died. In 20 other cases a late limited incision was made, and none of these patients died.

G. R. Turner read a paper on the surgical treatment of ascites at the meeting of this society held December 11th. Two patients were operated on by him. In one of them the upper and under surface of the liver was scratched, and the liver was stitched to the abdominal wall. In the other case, in addition to these procedures, the omentum was stitched between the liver and the parietes. This patient recovered, while the other was scarcely benefited, and when heard of four months later he had been tapped several times, and was then in bed with ascites of an extreme type. The patient who recovered was for some weeks troubled with pain in the region of the liver, and his spleen remained large for several months. The author of the paper insisted on the advantage of an early operation before the liver tissue had so degenerated that it cannot hypertrophy after the establishment of additional circulation. He favored an incision along the costal margin, and the introduction of the omentum between the liver and the abdominal wall.

At the Clinical Society, November 24th, Marsh read a paper on senile tuberculosis. He gave the history of a patient who at the age of 71 developed a suppurative arthritis of the left ankle. This was at first drained, but afterward extended up the leg so that amputation had to be performed. Then the right foot had to be taken off, for a similar affection of the ankle. Later the right knee-joint became affected in a similar manner, and amputation was performed through the thigh. These three operations were performed in a period of four years. Since then two years have elapsed in which there has been no further trouble. The disease in each joint evidently began in the synovial membrane, and led to complete destruction of the ligaments and cartilages. Marsh regarded this case as one of senile tuberculosis, a disease which in the aged has a tendency to remain localized, and has therefore a favorable prognosis.

At the meeting of December 8th, Barker made a communication based upon twelve consecutive cases of perforated gastric ulcer in which he performed operation. Five of the patients recovered. One died as a result of hemorrhage from the ulcer into the stomach. From this accident one might conclude that the ulcer should be excised, but it is evidently not a common accident, since this was its only occurrence in his experience. Wiping the abdomen, especially the under surface of the diaphragm, he preferred to flushing. Drainage was employed

only once, and then was not of any service. It was remarkable how slight the premonitory symptoms were. Several of these patients had complained of indefinite gastric pains only previous to the perforation; three gave a history of vomiting and two of hematemesis. In the five successful cases the interval between perforation and operation ranged from six to eighteen hours; while in the fatal cases it ranged from twenty-eight to seventy-seven hours. As to the diagnosis, there was in every case epigastric pain, but it varied in character. Collapse was present in only six cases. It seemed to depend on the character and amount of the extravasated fluid. Liver dulness was not always absent. The remote results after operation were good. In only one of the five patients were there symptoms which seemed to threaten a recurrence of the perforation.

SOCIETY PROCEEDINGS

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held January 6, 1900.

The President, Henry C Coe, M.D., in the Chair.

Strictures of the Eustachian Tube.—Dr. Arthur B. Duel read a paper in which he discussed the value of electrolytic dilatation for strictures of the Eustachian tube consequent to chronic catarrhal otitis media. There has been a remarkable change of attitude among otologists as to the treatment of chronic otitis media. Formerly, after a definite diagnosis, conscientious surgeons were apt to say that no remedy would be of any service, that the patient would probably grow deafer with time and that there was little hope of amelioration. After several regular practitioners have been tried with like ill success patients usually fall into the hands of charlatans and at least for a time enjoy the mental relief of having some hope held out to them, and having something done for their affection. Later it is realized that nasal and nasopharyngeal conditions were prominent factors in the production of chronic otitis media and that relief of the conditions in the throat and nose often brought improvement in the hearing. Sometimes the otitis media begins in the tympanum itself, but more usually it begins in the pharynx and spreads upward along the Eustachian tube. The narrower part of the tube is always seriously affected, its caliber is greatly diminished, or it is even occluded by the hyperemia which occurs. Later there is an exudation and the inflammatory products thrown out still further narrow the lumen of the tube and do so permanently. The ventilation of the tympanum suffers and this causes a hyperemia all through the inner aural passages. The chronic inflammation continues and the exudate organizes into connective tissue. Incurable deafness results as a consequence of the sclerotic process. Insufflation is of value in these cases, especially at the beginning, as it relieves the hyperemia. Its most important indication, however, is the ventilation of the tympanum. While inflation by the Politzer bag often suffices, the best method for most cases is the use of the Eustachian catheter. Where inflation fails, a stricture of the Eustachian tube usually exists. This is overcome in a good many patients by dilatation with bougies. Of late, however, electrolysis has been employed for this purpose, with excellent success. In urethral strictures it is well known that electrolysis often gives excellent results. It is from this that the suggestion came to apply a similar method to the ear. Electrolytic dilatation of strictures of the Eustachian tube was first employed in England more than ten years ago. Some six cases were reported in the *Lancet* as treated by this method, but since then it seems to have fallen into disuse.

Technic of Methods.—Neither of the English physicians who tried electrolytic dilatation of Eustachian strictures used a bougie which protruded more than an inch from the end of the Eustachian catheter. In recent work at the New York Eye and Ear Hospital a bougie that protruded an inch and a half, or more, according to the necessities of the case, was employed. The catheter was solid silver and was insulated by being wrapped with a piece of rubber tissue. It is in size about No. 3 or No. 4 of the French scale. The bougie is made of solid gold. The olive-pointed end fits into the aperture of the Eustachian catheter. Both instruments may be thoroughly sterilized by boiling. Before its use, to avoid infecting the tube, the nose and pharynx should be rendered as thoroughly aseptic as possible by the use of an antiseptic, such as Dobell's or Seiler's fluid. The bougie after the insertion of the catheter into the Eustachian tube should be introduced until it meets with an obstruction. No pressure should be used, but a current of from one to three milliamperes should be allowed to flow for a few minutes. Usually the instrument will pass after a short interval. If after from three to five minutes it does not, the current should be increased to five milliamperes. As a rule the bougie then passes the obstruction without pressure. Patients will tell of hearing bubbles in their ears which shows that the electric current is melting the sclerotic tissue of the strictured tube. At the New York Eye and Ear Infirmary where this method has been in use now for considerably more than a year some fifty cases have been tabulated. In all most satisfactory results have been obtained. Three typical cases may be given. The first patient, Dr. S., was troubled with increasing deafness and very bothersome tinnitus, which had been relieved for some years by treatment of the nosopharynx and by insufflation with a Politzer bag. Gradually the condition became worse and could not be relieved by these measures. On examination a stricture of the Eustachian tube was found. An

electrical bougie was passed, the current applied and the stricture promptly yielded. Inflations were practised for several days afterward and the patient was discharged completely relieved of his deafness and of the ringing in his ears. He has remained well for nine months practically without any treatment. Some tinnitus having recurred about two weeks ago he came back for inflation, which promptly relieved his symptoms. In a second case inflations failed to relieve the symptoms. The deafness was very pronounced, the tinnitus extremely annoying, and troublesome vertigo was present Before electrical treatment, a whisper could scarcely be heard at all. After the stricture had yielded and inflations had been practised for a day or two, a whisper could be heard at the full length of the room, twenty-four feet. The patient was warned that occasional inflations would be required, but he felt so well that he neglected the advice. About six months afterwards some of the old symptoms recurred. Only inflation was necessary to relieve them. After a time this measure was neglected once more. For over a year now there has been no recurrence of any of the symptoms. The third patient was a well-known singer in whom the bone conduction of sound was increased on both sides. Inflation improved the hearing on the left side, but had no effect on the right. After the passage of an electrical bougie on the right side, followed by inflation, his hearing which was very markedly defective was very much improved. Hearing on the left side was improved by the same treatment.

Progressive deafness is usually caused by atrophy and sclerosis of the tissues of the middle ear. The inflammation of the tube is only local and practically always produces a stricture. The indication is to remove this obstruction as soon as possible. The easiest, quickest, and most efficient method of accomplishing this is by electrolytic action. This method requires less force, there is less danger involved in it, and the bougie will pass after the current has been allowed to act for awhile. Often in these patients it would be impossible to introduce a cotton or other ordinary bougie. Strictures thus relieved do not recur. At least the experience at the New York Eye and Ear Infirmary justifies this positive declaration. Where temporary relief follows inflation, one can hope that the hearing may be entirely restored by the electrolytic method. All tubes should be opened when there is reason to think that their closure is an etiological element in the deafness.

Dr. Sturgis said that the use of electrolytic action in the treatment of urethral strictures has been practically abandoned, because of the danger of making false passages and because of the liability to recurrence and the great difficulty of dilatation after recurrence has taken place. It is very easy to make a false passage with the bougie in attempting to pass it through a stricture by the aid of electrolytic action, because the urethra deviates so much when strictures are of any considerable length. The destruction of tissue is followed by the production of scar tissue which has a very marked tendency to firm contraction and a constriction takes place that is much harder to pass than the first. Whether these same objections would hold against Eustachian electrolysis only experience can show.

Dr. Brandon said that he had been under Dr. Duel's care for deafness and tinnitus aurium and that all of his symptoms had been very much relieved by the electrolytic dilatation of his Eustachian tube. The sensations were not pleasant, but were not very painful, and the relief afforded had been very marked. The tinnitus was greatly lessened and his hearing very much improved. He had practically given up hope and had yielded to the idea that, like his father, he would have to submit to deafness as he grew older. Insufflation had failed before to relieve his symptoms, but now when there are slight recurrences inflation is of great service. The difference in the nature of strictures of the Eustachian tube and of the urethra makes it probable that recurrences will be very different in the two structures. There is not much soft tissue around the Eustachian tube to be affected by the current and so there is not the production of much scar tissue. As to a false passage, that would seem to be guarded against in the Eustachian tube by the presence of the bony canal.

Dr. Joseph Kenefick said that every day adds to the conviction that the electrolytic dilatation of the Eustachian tube is a brilliant discovery. It does cause some pain but complaint is made only by very nervous patients. Those who suffer most come back to have the operation repeated because of the relief afforded. There is no danger in the operation and it has solved a great and a difficult problem in otology.

Dr. Duel in closing the discussion said that there is no danger of making false passages in the Eustachian tube because very little pressure is used when the electric current is employed. Much less is used than in many other methods. It may be necessary to do the operation in two sittings. The first time the bougie may not pass, while the second time it will be found comparatively easy to pass it on. The indication is to open the tube.

Trumpet-Mouthpiece above Soft Palate.—Dr. Frothingham reported a case in which a child had swallowed the porcelain mouthpiece of a toy trumpet. At least the mouthpiece had disappeared from the child's mouth and caused symptoms of difficult breathing and swallowing. A number of physicians were consulted and a number of different forms of bougies employed to locate the object, all of which proved unsuccessful. When the child was brought to the Vanderbilt Clinic it was found that the mouthpiece was lodged above the soft palate in the nasopharynx. From here it had caused all the symptoms that had been noted yet had completely escaped observation. The probabilities are that it had been coughed into this position.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 4, 1900.

The President, Wm. H. Thomson, M.D., in the Chair.

Migraine as a Neurosis.—Dr. Coleman W. Cutler said on this subject: Heredity is the most prominent feature in the etiology of migraine. Sometimes the heredity is not direct, but the neurotic disposition is manifest in the ancestry or in the family and at times neurotic tendencies are replaced by other diatheses, such as the rheumatic, the gouty, or the diabetic. The most striking symptom of the disease is the aura. This is practically always present although other features of the disease may be absent, or may not be very prominent. The most important auræ are those in the visual sphere, usually bizarre light effects, bright muscæ volitantes, fortification figures, or showers of stars. More rarely other aura are noted, as, for instance, peculiar odors entirely subjective in origin; at times subjective tastes. Leyden has recently reported a case of recurring metallic taste just before an attack. Then there are at times various paresthesiæ that replace the visual aura. Defects of memory and paraphasia have been noted as preceding attacks of migraine. The disease does not always occur regularly, that is, at regular intervals, but may follow certain definite causes. A prominent physician in the city always has an attack of migraine after taking any unsual exercise. He takes advantage of this fact to anticipate his recurring attacks of migraine. Whenever he has any important duties at a definite time he deliberately brings on an attack by taking a certain amount of unusual exercise and then he is sure that he will be free from the affection for some weeks. He finds that he is able to control most of the discomforts of an attack by a quarter of a grain of morphine. This does not produce sleep, but allays the discomfort. It must not be forgotten that attacks of migraine may be initial symptoms in such diseases as tabes, general paresis and brain tumor. When a first attack occurs late in life suspicion should be aroused as to the existence of some organic lesion of the nerve centers. This must be especially borne in mind if the patient is not of a nervous disposition and there is no special neurotic family history.

Glaucoma and Migraine.—Great care must be exercised in the differential diagnosis of glaucoma and migraine. Time is very precious in the former affection and a day or two of delay may mean the loss of vision. It is sometimes advised to use the ordinary remedies for migraine and then if they do not succeed to suspect the presence of glaucoma. This advice is bad and may easily cause permanent loss of sight. In cases of migraine the tension of the eyeballs should always be carefully tested. Especially must this be done if patients come with a first attack of what seems to be migraine. In general it is to be remembered that eye defects have an important bearing upon the existence and persistence of migraine. All discoverable visual defects should be corrected. Other sources of peripheral nerve irritation should also be carefully looked to. It is not enough to correct astigmatism, but adenoids should also be removed and hypertrophied turbinated bones should be properly treated. It is curious to note that all of these sources of peripheral irritation are distinctly hereditary in many families and as heredity is the most important etiological element in migraine, the relation between such conditions and the affection almost immediately suggests itself. The subject of migraine and neurotic equivalents is too large for discussion as a part of a paper on migraine. It is well known that certain of the minor neuroses occur in patients who suffer from migraine. The question of the relationship of migraine and epilepsy has been much discussed. They are certainly very similar, although the best authorities are now agreed that they are not the same affection. As to the connection between migraine and the gouty diathesis there is a good deal of difference of opinion. Trousseau thought that he never saw migraine without being able to find some traces in the individual of chronic gout. Moebius declares that he has never seen migraine in gouty patients. It is evident that the truth lies somewhere between these two extreme opinions. That both conditions are distinctly hereditary is, of course, well known to all.

Treatment.—Notwithstanding the number of drugs that have at various times been recommended as specifics for the treatment of migraine there are practically no pharmaceutic preparations that can be depended on either to relieve the symptoms or to increase the intervals between the attacks. The usual rule is that, after long experimentation with different remedies, victims practically give up drug taking and become resigned to sacrifice a day to the affection when it occurs. Various nerve sedatives serve to lessen the discomfort. Lithemia is set down by some as a cause of the disease and treatment for the condition is sometimes instituted with asserted success. Lithemia itself is, however, a most indefinite condition and the treatment is not very settled. Many cases of migraine are benefited by the oculist. About fifty per cent. of the cases will be at least improved by the correction of visual errors. Notwithstanding all that has been said of recent years with reference to the significance of muscular defects of the eye in connection with migraine, it is usually the correction of errors of refraction that brings improvement. There are certain cases, however, in which the correction of the muscle balance helps the migraine.

Is Migraine a Neurosis?—Dr. Wm. H. Thomson questions whether migraine is really a neurosis. It seems rather to be an intermittent toxemia due to specific poisons which are ab-

sorbed from badly digested material in the intestinal tract, or to the imperfect neutralization of such toxic substances in the circulation by a defect in the ordinary antitoxic processes that accomplish this purpose. One thing is very queer. All out-of-door workers are exempt from the disease. While the affection is much more common in women than in men, it does not occur among women who work in the fields in certain countries. Its favorite victims are those who spend most of their lives indoors and at a sedentary occupation. Outdoor work prevents stasis in the portal circulation, while sedentary indoor occupations rather favor it. It is evident that there is here an important etiological factor in the disease. And the old idea that migraine is a pure neurosis must not be permitted to have too much weight either in the consideration of the pathology, pathogeny or treatment.

Migraine and Graves' Disease.—Migraine occurs much more frequently in people who are afflicted with Graves' disease than is usually considered to be the case. This connection between the two diseases serves to throw light on the etiology of both of them. Graves' disease itself is much more frequent than it is usually thought to be. The affection may occur entirely without exophthalmos and without any enlargement of the thyroid gland so that the name exophthalmic goiter is a misnomer. It is probable that there are at least as many cases of Graves' disease without prominent eyeballs and enlarged thyroid as with these symptoms. It has been the custom to speak of such cases as latent Graves' disease, but this name is unsuitable since there are certain characteristic symptoms of Graves' disease present which can easily be demonstrated. Out of sixty-five observed cases of Graves' disease thirty-two were without exophthalmic goiter, while thirty-three had these symptoms. All of the cases had the persistent tachycardia, which is so essential to the disease, and most of them had the nervousness, the tremor and the digestive symptoms. The nervousness of the disease is often described by patients as a sense of fear which they themselves feel to be without reason. The tremor is nearly always worse in the morning and may disappear towards evening. Of these sixty-five cases in only five was the tremor not worse in the morning. Vague peripheral pains are frequently present and sometimes there are spots of hyperesthesia. At times the ears are tender to the touch, and this symptom may be one-sided. The evil of naming an affection from some one prominent symptom which is not essential to the disease is brought out very clearly by the mistakes of diagnosis which occur with regard to Graves' disease. To the ordinary student and the general practitioner Graves' disease is exophthalmic goiter. Where these two symptoms, the exophthalmos and the goiter are absent, there seems nothing to suggest the diagnosis is Graves' disease. The same thing happens in locomotor ataxia when that disease begins without an incoordination of gait.

In four fatal cases seen in recent years all the patients suffered for a considerable length of time before the Graves' disease was recognized. All died by simple stoppage of the heart and without a struggle. Three had no goiter at the time of death.

Graves' Disease an Autointoxication.—It is now pretty generally conceded that Graves' disease is due to the presence of toxins in the circulation. It was formerly considered that these came from the enlarged thyroid, but this idea has been practically abandoned since it is now realized that Graves' disease exists without an enlarged thyroid. The most probably theory for the etiology of the disease seems to be that it is a malassimilation of nitrogenous material by the system, just as diabetes is a malassimilation of the starch elements of the food. The unassimilated nitrogenous substances are toxic and are ordinarily destroyed by the secretory activity of the thyroid, hence the frequent enlargement of this organ to meet the increased functional necessities. Sometimes the irritation of the thyroid instead of leading to hypertrophy, leads to atrophy of the gland with consequent myxedema.

In a recent case of combined Graves' disease and epilepsy, in which the patient had suffered from the age of seven until she was eighteen with epilepsy, the convulsions disappeared under treatment. Later exophthalmic goiter appeared and this has now given place to distinct attacks of migraine. Out of thirty-two observed cases of Graves' disease without goiter and thirty-three with goiter in twenty-six and twenty-eight respectively headache was present, and in 65 per cent. of all the cases this headache took on the distinct characteristics of migraine. A prominent feature of both migraine and Graves' disease is that they are associated with gastric disturbances. Both of them are distinctly influenced by heredity and occur by preference in neurotic families. Of all the pathological conditions that are inherited, gastric idiosyncrasies are the most common.

Migraine as a Neurosis.—In the discussion Dr. Charles L. Dana said that migraine is the most common of the neuroses. Probably every physician has either experienced it in person or has seen it in some of his ascendants or descendants. It is a discharging neurosis, involving higher nervous centers than does epilepsy. It is especially in the cultured that the sensory centers are liable to be unstable and it is in these particularly that migraine occurs. Eye treatment sometimes does good, but certainly not in more than ten per cent. of the cases that come to neurologists, although, of course, these are mostly cases that have been under treatment by others. The antitoxic treatment by the salicylates and resorcin undoubtedly does good. But this does not seem to be so much because these drugs prevent an autotoxemia, as because they lessen the irritability of sensory nerve centers. Migraine is undoubtedly common in Graves' disease and the calling attention to this fact is of great practical

interest. The connection between the two diseases, however, does not militate against migraine being a neurosis. The fact that it has certain neurotic equivalents shows that it is surely of nervous origin. Every neurologist has seen the attacks of migraine occasionally replaced by such purely nervous affections as ptosis or Meniere's disease. Dr. Sachs said that to consider migraine as a toxemia rather than a neurosis is purely speculative. While many people suffer from toxemia only certain people with a predisposition have attacks of migraine. The neurotic equivalent for migraine seems to show that it is certainly a neurosis. In a recent case, after the disappearance of epilepsy, migraine asserted itself. Whether the opposite ever happened is not very clear. The relation of migraine to Graves' disease is problematic and the two occur together rather rarely. To call tachycardia, without any other symptoms Graves' disease is at least risky. Other symptoms are necessary for the diagnosis.

In closing the discussion Dr. Thomson said that simple tachycardia never means Graves' disease for him. There must always be present certain other characteristic symptoms, such as tremor and the digestive symptoms, either diarrhea or constipation, with the vague pains and paresthesia of which previous mention had been made.

NEW YORK ACADEMY OF MEDICINE—SECTION ON SURGERY.

Stated Meeting, Held January 8, 1900.

Charles N. Dowd, M.D., Chairman.

Aneurism of the Innominate.—Dr. Fiske presented a woman, forty years of age, who first began to complain of symptoms in her thorax last March. There is now a distinct tumor to the right of the sternum in the subclavicular region, in which there is marked pulsation and a distinct aneurismal bruit. There is also some difficulty in swallowing and some huskiness, showing involvement of pharyngeal and laryngeal nerves. The patient has been under medical treatment since last March, but has not been benefited.

Dr. Bolton said that gelatin injections had been tried in this case, but without benefit. They had been tried also in four other cases and in none of them had the beneficial results claimed by the French surgeons been secured. They gave great pain and sometimes caused distinct rises of temperature. It is evident that they are not entirely without danger since after one injection the temperature rose to 104° F. At the Hudson Street Hospital the conclusion is that the gelatin treatment is of no service.

Sarcoma Cured.—Dr. Coley presented a patient who developed some four years ago a tumor of the parotid gland. It was removed and proved to be a sarcoma. It recurred in the same situation and was again removed. It then not only recurred in the parotid, but also in the sublingual and in the submaxillary glands. When the tumor reached a circumference of from three to four inches and extended from the auditory meatus almost to the angle of the mouth, it began to ulcerate. The patient was then sent to Dr. Coley and he found in addition to the parotid tumor a submaxillary tumor the size of a hickory-nut. It was hopeless to operate again and so the mixed toxin of erysipelas and the bacillus prodigiosus were injected. As the case was a very severe one the injections were made directly into the tumor and in very large doses. There was considerable reaction after the injection, the temperature on several occasions going as high as 104° to 105° F. Slight improvement in the symptoms and some diminution in the size of the tumor were noticed at the end of a week. In ten weeks the growths had completely disappeared. It is now two and one-half years since the beginning of the treatment and there has been no recurrence. The man is in perfect health and there is only a scar to mark the place where the ulceration occurred on the surface of the tumor.

Dr. John A. Wyeth asked if Dr. Coley thought that the infective agents at work in such a case might not have something to do with the cure. When tumors are suppurating the injection of toxins often leads to an increase in the virulence of the suppurative process already existing. The absorption of infective material from a suppurating focus might be the real agent at work. Dr. Coley replied that where suppurating foci exist he is always careful to cleanse them as thoroughly as possible and that his experience does not show that such suppurative processes become more intense while the injections are being made. In a recent case he had the opportunity to assure himself that cure took place absolutely without the presence of any infective agent. In the mixed toxins the bacilli are carefully removed before injection. A large tumor of the thigh gradually disappeared under the injection of the toxins with the production of certain cystic cavities. From these cavities broken-down tumor débris was removed by aspiration and absolutely no pyogenic agents could be demonstrated in the material so removed.

Dr. Wyeth reported a case of a large tumor of the abdominal wall in which Dr. Welch, Dr. Wardwell, of Cohnheim's laboratory, and himself, had each independently made the diagnosis of sarcoma. It was so large that it seemed hopeless to attempt to remove it. At the time certain cases of sarcoma had been treated with reported success by injections of arsenious acid. The remedy was tried. It set up an intense inflammatory process. Septicemia developed and for a while it seemed as though the case would inevitably terminate fatally. After being very low, however, the man began to recover and with his recovery the tumor began to disappear. When convalescence was complete no sign of the tumor was left. That was fifteen years ago. The man

is alive and well, in one of the Southern States and is able to do a hard day's work. In a case that came under observation about eight years ago an immense tumor of the omentum was present. This pressed on the portal vein so much that ascites developed and the patient had to be tapped every few weeks. An exploratory laparotomy was done although there was scarcely any hope that the tumor would prove operable. The growth was found to be a very vascular neoplasm with large thin-walled vessels running over its surface. The neoplasm was so succulent that no section of it was made for purposes of microscopic examination. Whether it was a sarcoma then or not, was not certain, but it had all the clinical signs of a sarcoma. The wound was left open and the tumor exposed to the air, the general abdominal cavity being protected as well as possible by packing. Suppuration took place and the tumor gradually disappeared. The patient is now living and no signs of the tumor remain. It would seem, then, that while there is no doubt that the toxins of various micro-organisms can produce a beneficial effect on sarcomatous tissue and cause its disappearance, this may also happen as the result of the presence in the circulation of materials absorbed from ordinary infective processes. What element in the infection it is that causes the disappearance of the sarcoma is as yet in doubt. The subject is well worthy of a further attentive study. Dr. Coley is to be congratulated on the light he has thrown on this subject, and the excellent work he has done in bringing the matter before the profession in America in a thoroughly scientific manner.

Intestinal Resection; Recovery.—Dr. Coley presented a patient, a physician, forty-three years of age, who in May, 1899, suffered from a series of attacks apparently of chronic appendicitis. An operation for this was performed and it was found that the cecum was infiltrated with neoplastic tissue which had also spread to the small intestine. The removal of the whole growth seemed too radical a procedure, so nothing was done. Some weeks later the whole mass was removed. The ilium was resected in its continuity and an end-to-end anastomosis made with a Murphy button. After the removal of the cecum the ascending colon was closed by a row of sutures and also the distal end of the ilium. Then the two structures were connected by a lateral anastomosis, for which an oblong Murphy button was used. Recovery took place without an incident and on the tenth day both buttons came away. There have been no symptoms since except that occasionally after meals there is an accumulation of gas which can be relieved by simple external manipulations. The patient has regained his health, strength and weight. There are no signs of the recurrence of the growth and allowing for the short time elapsing it would seem that a radical cure has been effected.

Aortic Aneurism.—Dr. John M. T. Finney of Baltimore read a paper on the treatment of this condition, which he thinks should be surgical. The Tufnel treatment has benefited some cases, but they are very rare. The cures that have been announced are even rarer and we have not any assurance as to their persistence. For vessels of medium size it is questionable if any treatment except operation is justified. The Hunterian operation in these cases gives excellent results. As to aneurism of the abdominal aorta, this is very different. Nine cases in which the abdominal aorta has been tied have all proved disastrous. A case in which Keen tied the abdominal aorta and in which the patient survived is reported. This case is a recent one, however, and the details are not substantiated. MacEwen's operation of needling the internal wall of the sac, so as to lead to the formation of an internal thrombus sometimes gives good results, but it is slow in its operation and cannot always be relied on.

Gelatin Injections.—The injections of gelatin suggested by the French surgeons have not proved as successful as was promised. The brilliant results have been obtained nowhere else. Dr. Futcher has experimented with the method at Johns Hopkins Hospital in nine cases. In six of them the treatment has been carried on for a sufficiently long time to give definite conclusions as to the value of the procedure. No positive cures have been obtained in any of the cases. In one there was diminution in size of the aneurism. In five cases the patients were subjectively better. The injection of gelatin did not add to the coagubility of the blood. This was demonstrated by careful tests. Despite Lancereaux's assurances that the injections produced no discomfort, they were usually accompanied by considerable pain and sometimes followed by fever. There was never any local suppuration and only in one case was there a local reaction. The gelatin method does not cure, but it is of some value in certain cases. In conjunction with the wire method it is better than either one of them alone. Where it seems inadvisable to use electrolytic methods hereafter, it is advisable to combine these two methods.

Coiled Wire and Electrolysis.—The most effective treatment for aneurism is undoubtedly the insertion of wire and the electric current. As to the wire that should be used it has been found at Johns Hopkins that a silver alloy highly drawn is the best for this purpose. The alloy is composed of 75 parts of copper to 1000 parts of silver. When highly drawn this wire, unlike pure silver, retains considerable tendency to coil within the sac and yet is more pliable than any other form of wire, so that there is much less danger of puncturing the sac. If anything causes the wire to become blocked or it kinks another needle may be inserted at some little distance from the first and wire passed through this. If there is a multilocular sac a series of wires may be passed. The direction of the wires should as far as possible be away from the neck of the sac and in the same direction as the incom-

ing current of blood. The positive pole should be attached to the wire within the sac, not the negative pole. The negative pole causes the formation of a clot which breaks down easily.

Danger and Results.—Sepsis is the omnipresent danger in wiring an aneurism. The point of insertion of the needle should be rendered as aseptic as possible. There is some danger of the development of an additional aneurismal sac by a change in the direction of the blood stream and the setting up of a current against a part of the sac which was not acted on before. The current should not be allowed to act through the needle itself. For the purposes of insulating the needle it has been found that a French lacquer acts very well. At times the wire passes out of the sac itself and causes complications by the formation of clots in the blood stream which may give rise to thrombi in the general circulation or interfere directly with the heart action or with the valves. In some reported cases the impinging of the wire on a valve has caused death. In others the interference with the valvular mechanism has led to syncope. It has been said that the presence of a distinct double diastolic and systolic sound shows that the sac has a small opening. Halsted, however, found on autopsy in a case in which there had been a distinct and characteristic aneurismal bruit that the opening was a large one, so that this diagnostic rule does not hold in all cases. The danger of perforating the sac has been exaggerated. As a matter of fact, when suitable wire is used it coils up and does not produce the slightest traumatism.

The reported results of the use of wire and electrolysis on large aneurisms certainly justify the continued employment of this method of treatment. At least twenty per cent. of the reported cases have been cured. Dr. Stewart of Philadelphia wired one of his patients three times and the patient felt better each time. Hare's case has continued well ever since the operation. In other recent cases persistent results have been at least as good. The great drawback, so far as statistical hopes are concerned, is that the cases which are wired are not selected cases, but are hopeless cases in which a fatal termination seems not far off unless something is done. As a matter of fact, wiring completely changes the aspect of some of the patients and makes them hopeful. One patient was a most pitiable picture. He could not lie down at all, but took whatever rest he could get sitting bolt upright and there was a continued feeling of the most severe discomfort. At the present time this patient can lie down and considers that he has been practically cured. In another case the right chest filled up frequently with fluid and required repeated tapping. The accumulation of fluid in the pleural cavity is now much less than it was and tapping is not so frequently required.

Distal Ligatures for Aneurisms.—Dr. Wyeth discussed some of the older methods of treating aneurisms and their successful application. In one of the old cases Sands tied the subclavian and carotid arteries of the right side. The tumor diminished in size and all visible pulsation ceased. For some time all the subjective symptoms disappeared. After three months there was a recurrence with fatal termination. In the same way the common carotid has been tied with the induction of undoubted relief. In a number of cases within the past fifteen years distal ligature has been accomplished successfully, both as regards the operation itself and its effect upon the aneurism. Even where the innominate was involved in the aneurism, such ligations have been successful, so that they are not contraindicated under these circumstances. This method of treating aneurism should not be allowed to sink into desuetude. His experience with wiring has not been very great. Once by a method analogous to the use of wire the life of a patient was saved. He was a young man of twenty-four who came to the Polyclinic with a huge pulsating tumor in the upper part of his thorax. There was a balloon-like dilatation of the skin, the aneurism having fretted its way through the sternum and through two ribs. It seemed to be on the point of bursting and quick action appeared to be demanded. Some harelip work was being done that afternoon and twenty-five sterilized harelip-pins were at hand. One by one these were plunged into the tumor, just as if it were a pin-cushion. Eighteen hours later they were removed. The effect was excellent. The tumor sank almost to the level of the thorax, having bulged out a great deal before, and the subjective symptoms were much lessened. Twenty-four hours after their removal they were once more inserted and left in for twelve hours. Then the patient was kept absolutely at rest and put on potassium iodide for some time. The pulsation disappeared and the patient remained comfortable and was able to work as a painter for a year and two months, when he died suddenly, apparently from cerebral embolism. Before the introduction of any foreign body into an aneurism, however, a thorough trial of the Tufnel treatment is advisable. The prophylactic treatment of syphilis should be borne in mind and extensively taught to the public.

THE CHICAGO MEDICAL SOCIETY.

Recent Meetings.

Blastomycetic Dermatitis.—Dr. Henry G. Anthony reported an interesting case of this disease before the December meeting of the Chicago Medical Society. The report of the pathologist, Dr. M. Herzog, on this case is as follows: "Histologically, the tissue presents a proliferation of the epithelial elements, which proliferation extends downward into the connective tissue in the form of pegs, such as are seen in skin cancers. The following may be points of differential diagnosis between skin cancers and blastomycetic dermatitis. In the latter epithelial cells are

not cut off anywhere from the surface in the form of closed alveolar nests, nor do the proliferated epithelia become hornified. That seems to be quite an important feature. In skin cancers the proliferating epithelium shows an early tendency to become hornified. In the sections of this case, we do not see any true epithelial pearls. In the epithelial masses you see small miliary abscesses which contain leucocytes, ordinary polymorphous leucocytes and a great number of eosinophilic leucocytes; it is particularly in the miliary abscesses that the yeast cells are found in the shape of double contoured bodies. The cutis proper is characterized by a great deal of inflammatory reaction, and among the cells infiltrating the tissues are a large number of typical plasma cells. I have also found in some of the miliary abscesses giant-cells of a type such as are found in tuberculosis. I have stained and examined sections for tubercle bacilli and other bacteria, but have not found any. I must also say that I have not found anywhere anything characteristic of syphilis, but as I had only a very small piece of tissue, I could not make any special stains for syphilitic lesion.

"The histological features which are found are absolutely in accord with the pathology of the cases of blastomycetic dermatitis described by Hyde, Bevan, Hektoen, Gilchrist, Buschke and others."

Goiter with Recurrent Paralysis.—Dr. A. C. Klebs presented a patient with a "forme fruste" of exophthalmic goiter with tracheal stenosis and recurrent paralysis. The patient was a young man, twenty-two years of age, in whom, of the three cardinal symptoms of Graves' disease, only the struma was well-defined. Pulse ranged from 92 to 102. Exophthalmus was not very marked. The signs of Stellwag, Graefe and Moebius were absent. There was a slight tremor of the hands, and inclination to perspiration, palpitation, nervous irritability and headaches. The struma was rather hard and pressed on the trachea, which was bulged in; there was paralysis of the left posticus, hence difficulty in respiration (stridor) and phonation. There was no distinct improvement after five weeks' rest. Iodides and faradism have been resorted to without much benefit. The author believes that partial extirpation of the struma is indicated.

Gunshot Wound of the Abdomen.—Dr. Jacob Frank reported this case at a meeting held January 10th. The patient, Mrs. A., mulatto, aged twenty-three years, and was admitted to the German Hospital July 26, 1899. She was accidentally shot with a 38-caliber revolver about 1:30 P. M., and was brought to the hospital four and a half hours later. The bullet entered the abdomen in the left hypochondriac region, two inches below the last rib on the left axillary line. No wound of exit was found. She complained of slight pain, which was referred immediately back of the point of entrance of the ball in the region of the kidney and about the uterus. She thought the pain about the uterus was due to menstruation, but as the bullet was found in the cul-de-sac of Douglas, the increase of pain is well accounted for here. The patient was in good condition; the pulse strong and regular; no emesis, faintness nor dejection from the bowels. There had been but little hemorrhage; no distention of the abdomen, and percussion and palpation failed to locate the bullet. From the position in which the bullet left the pistol and from its entry, it was determined that it would be almost impossible for the ball to travel in said direction without injuring the intestines. The patient was anesthetized, the bullet wound was enlarged and the finger introduced with the hope that the track of the bullet might be followed. Failing to detect the ball, or an opening in the peritoneum, an incision six inches long was made to the left of the median line on the outer border of the rectus muscle, beginning one and a half inches above the umbilicus and extending downward and inward toward the mons veneris. Upon opening the abdomen a small quantity of fluid and some blood were found, but no escape of intestinal contents. The patient was eviscerated from the pylorus, the parts being protected by warm towels, the injuries to the intestines being noted and marked with a piece of gauze pushed through the mesentery. Examination showed that the bullet, after penetrating the walls of the abdomen and perforating the walls of the small intestines besides bruising two or three other portions, as was shown by a marked ecchymosis, had dropped in the cul-de-sac of Douglas, whence it was extracted. A small bleeding point was found a short distance away. It was found impossible to repair the perforating wound with sutures in the gut. Resection was therefore made and a one and one-eighth inch Frank's coupler introduced and the anastomosis completed in the usual way. The bruised portions were closed with Lembert sutures. A gauze drain was introduced in the bullet wound incision. At the upper end of the laparotomy incision, a gauze drain was inserted, and at the lower end a modified Mikulicz drain was introduced into the cul-de-sac and removed after thirty-six hours. There was very little shock following the operation, and the patient rallied nicely from the anesthetic. Her recovery was uneventful, and on October 8, 1899, thirteen days after the anastomosis, the piece of rubber tubing was passed. The patient left the hospital October 23, 1899, and has enjoyed her usual health ever since.

Venous Angioma.—Dr. D. N. Eisendrath presented a case of congenital nevus, involving all of the fingers of the right hand in a child five years of age.

Gangrene Following Schede Operation.—He also presented a case of gangrene of the foot following a Schede operation for the relief of varicose veins combined with ligation of the internal saphenous vein. The patient was forty-three years old, moderate drinker, with no history of venereal disease, but with well-advanced arteriosclerosis. The urine was free from albumin or

sugar in a number of examinations. The above operation was performed in December, 1898, shortly after which the patient had severe pain in the second toe, which became black and lifeless about four months after operation, necessitating its removal. The wound never healed, and in May, 1899, the third toe had become dark bluish-red in color, and the former amputation surface black. There was also a black irregular shaped patch extending upward on the dorsum of the foot about three inches long and about one inch wide. Palliative treatment being of no avail, it was necessary to perform a Pirogoff amputation in June, 1899. Patient presented himself to Dr. Eisendrath about two weeks ago. The amputation stump at this time was dark bluish in color, and there was an ulceration at the apex of the stump, so that it looked at first as though an amputation higher up would be necessary. The limb was edematous below the level of the Schede operation. There were no traces of any varicose veins. There had never been any ulceration. The patient was not shown to throw discredit upon this operation, which has given most excellent results in the majority of cases, but simply to call attention to the fact that it may be, at times, followed by complete venous stasis and gangrene, and that the operation is not to be advised when there is much arteriosclerosis, or when the return circulation will be at all impeded.

Unilateral Surgical Kidney.—A third case was that of a patient who had been operated upon one and one-half years ago on account of a pyelonephritis, with excellent recovery. The other kidney had remained apparently normal and the urine was clear. The patient had been treated with antitoxin for diphtheria since that time, and had also undergone an operation for cystic ovary. The case was chiefly instructive on account of the fact that the general teaching is that surgical kidney is most frequently bilateral, and such cases as the above show that nephrectomy for such conditions offers a good prognosis. A specimen of surgical kidney was also shown, which had been removed at autopsy from a woman who had suffered from a cystitis and in whom the opposite kidney was also found to be perfectly normal.

At the meeting held January 17th there was a symposium on disinfection.

Preparation for Disinfection.—This was discussed by Dr. C. Fenger. In preparing a patient for an operation it is customary to have him or her in the hospital for from twenty-four to forty-eight hours previous to operation, the object being threefold—mental, physical, antiseptic. During this preliminary stay in the hospital the patient has an opportunity to become accustomed to hospital-life, and to overcome anxiety. The patient rests in bed or lounges about the room as inclination or circumstances may dictate. Few, if any, visitors are admitted. During this time the physicians in attendance become acquainted with and accustomed to any peculiarity or idiosyncrasy which may prove of aid in the after-treatment. The stomach and intestinal tract should be carefully looked after and efforts made to correct any abnormality or irregularity in their action. There is no difficulty in getting absolutely sterile instruments, ligature and suture material, sponges, dressings, clothing, etc. The real danger of infection is in the incised skin of the patient or in the hands of the operator or his assistants. The chief aim in the preparation of the skin is the mechanical removal of the masses of loose epidermis with bacteria. This is best accomplished by means of soap and water and a stiff nail-brush. Too much confidence is placed in so-called antiseptics. To a greater or less extent they are all poisonous, and if used in a solution of sufficient strength to kill germs will do damage to the tissues with which they come in contact, and if so weak as not to cause damage to the skin, are frequently of little or no value as bactericides.

Schleich's Skin Sterilization.—Dr. E. Wyllys Andrews read a short paper on this subject. Exhibition of Schleich's marble dust soap was made, and its use illustrated. Schleich lays down the emphatic rule that brushes should never be used, as they are incapable of being cleaned and therefore become "labyrinths of filth and slime." In his method chemical antiseptics are given an unimportant place. They tend to injure the skin and do not effectually sterilize it. The properties required in a good soap are: (1) Sterile materials; (2) detergent properties, hence the use of marble dust; (3) some ammonia to act as a liquefying agent or flux, the soda or potash being too hard when saponified; (4) fat emulsifying power to carry away the waxy deposits of the skin (cholestrin, keratin, etc.), for which purpose he introduces what he calls "stearin paste"; (5) wax, free in the mass, to leave the skin anointed, for which purpose so-called "cerate paste" is put in the soap; and (6) sterile running water.

The soap is a white paste of gritty feel. It is applied by rubbing with squares of sterile gauze made into small napkins. A wax-like feel is left after it has been washed away. Personally, Dr. Andrews testified that it is less irritating to the skin than green soap used with a brush.

Operator and Assistants.—The following method is practised by Dr. Jacob Frank in his work at the German Hospital: The operator and assistants change their garments, putting on white duck trousers and sterilized shirts. The head and beard are covered by sterilized gauze. The operator and assistants scrub their hands and forearms for fifteen minutes with sterilized green soap and running water, finger-nails having been previously cut short, are cleansed by nail-file. If the operation is a laparotomy, the hands are sterilized by being immersed in a saturated solution of potassium permanganate, followed by a warm saturated solution of oxalic acid. This is followed by sterilized lime-water, and lastly sterilized water, known as Kelly's solution. In all other cases Kelly's solution is omitted. The

hands are scrubbed from three to five minutes in a $^1/_{1000}$ bichlorid of mercury solution, followed by alcohol and sterile water. Rubber gloves are used in all operations. The operator and assistants disinfect their hands in the same manner and for as long a time as if the gloves were not used. The gloves are first thoroughly washed both inside and out in a one-per-cent. solution of sodium carbonate, then rinsed in sterile water and dried by holding over a gas flame for one minute, reversing once. The inside is dusted liberally with soapstone powder which has been previously sterilized by dry heat for two hours. The gloves are wrapped in a double layer of gauze, marking the size on gauze, and placed in a formaldehyde sterilizer for two hours. After removing the gloves from the sterilizer they are wrapped in a sterile towel, the size and date of sterilization being marked on outside of towel. After the hands have been disinfected, as already stated, they are dried in sterile towels, the field of operation is prepared by a second nurse, and covered by laparotomy sheet or sterile towels, the operator and assistants putting on sterile gowns. Everything being ready to begin the operation, the gloves are slipped on. The object of such thorough preparation of hands previous to operation is that in case the gloves become torn during the operation, the hands still remain sterile. Sterilized finger-cots are always on hand in case the finger of a glove becomes torn. This method of sterilization of gloves has been found to be far superior to all others. In the first place, the gloves are sterile. Cultures have been made repeatedly, immediately and two weeks after sterilization, and they have shown absolutely no growth of life. Pure cultures of staphylococci, streptococci, bacillus coli, Klebs-Loeffler bacillus, bacillus typhosus, bacillus pyocyaneus, etc., after having been passed through the formadehyde sterilizer, have shown no life. In case of abrasions of forearm, rubber armlets are used, which are sterilized in the same manner as the rubber gloves. After the gloves have been used they are re-sterilized.

Woven Gloves.—Dr. Coleman G. Buford, a former assistant of Professor Fenger, after nearly two and a half years of observation of the use of gloves in Professor Fenger's operations, concludes that woven gloves have a place in dry operations, and that the outer surfaces of dry gloves usually remain sterile throughout the longest operations. He perfers cotton to silk gloves, but recommends above all the use of rubber gloves, because of their impermeability. Both the woven and rubber gloves are sterilized in any of the usual ways, except that he advises against boiling the rubber gloves in soda, or in carbolic acid solutions stronger than two per cent. A hundred and twenty-five bacteriological examinations were made, and the writer's conclusions are that, in proportion to the work and responsibility of those engaged in the operation, there is a relative increase or diminution in the frequency of cultures from the inner side of the gloves. This is probably due to reinfection of the surface by bacteria brought from the sweat-ducts, glands and hair follicles by perspiration sponsibility of those engaged in the operation, gloves were infected in 66⅔ per cent. of the cases, while the least active person, the nurse handling sutures, ligatures and sponges, had no cultures from the inner side of her gloves. A total of 63 cultures were made from the inside of the gloves of all participants, and there was infection in $28\,^4/_7$ per cent., while of the 62 cultures made from the outside, only $9\,^{21}/_{31}$ per cent. were infected, and the latter occurred with no more frequency in the case of the operator than with the assistants. Staphylococcus albus was the only microbe found. The writer reports but one case of accidental infection during the use of the gloves—a mild albus infection of an inguinal hernia. Stitch-hole abscesses are almost a thing of the past, and wound healing is more perfect and speedy than when the gloves are not used.

He suggests that, in addition to the gloves, the operator sterilize his hands in his own accustomed way, then sweat the hands and forearms for fifteen minutes by immersion in hot water or exposure to dry steam, a second hand sterilization and sweating, then a final hand sterilization. This has been proven worthy of consideration by experiments of Dr. Leonard Freeman; that woven finger-cots be worn by the operator over the glove-fingers on each thumb, and one or more chosen fingers to facilitate in handling tissues, to prevent cutting by ligatures; and that, finally, sterilized armlets of rubber or cloth be used to cover the arms and enclose the glove gauntlets to prevent leakage of fluids from the gloves into the operative field and to prevent contact of gloves with neighboring forearms.

Surgical Disinfection in the Augustana Hospital.—The following conclusions expressed the views of Dr. A. J. Ochsner: (1) Theoretically, it is almost impossible to thoroughly and absolutely disinfect the skin of the patient and the hands of the operator. (2) Practically, it is one of the easiest and simplest tasks to obtain a degree of surgical cleanliness that will insure primary wound healing. Theoretically, strong chemical disinfectants are indicated for the purpose of disinfecting the hands. Practically, careful washing with the mildest soap and water and alcohol is absolutely sufficient and very much safer for the patient, because hands roughened by the use of strong antiseptics are much more likely to become hopelessly septic than those which are covered with smooth, healthy skin. (3) It is extremely simple to keep the hands aseptic after they have been rendered so. There is no more difficult task in any clinic than to keep all interested hands clean after they have been disinfected. (4) Sutures passing through the skin and the deep tissues underneath are a menace to the patient, because they form a direct communication between the skin, containing staphylococci, and the deep tissues, which are primarily sterile. These stitches never cause an

infection unless drawn too tightly, in which case the resulting pressure necrosis is the cause of the mischief, because it furnishes these micro-organisms dead tissue to thrive upon. Catgut sutures and ligatures are objectionable. Practically, if applied properly, they are absolutely satisfactory. (5) Theoretically, it is as safe to operate clean cases after dressing suppurating wounds as at any other time. Practically, surgeons who follow this practise always have a great amount of wound infection.

Dr. W. E. Schroeder gave his views on the construction of an operating-room, its furniture, the management of jars, towels, sheets, gowns, rubber aprons, Kelly pads, and a number of small details.

Drainage.—Dr. A. E. Halstead spoke on this subject, saying that the subject of drainage of wounds naturally falls into two divisions. (1) The drainage of wounds which are surgically clean, or are supposed to be such; (2) the drainage of wounds which have been infected, or which are made to relieve suppuration or septic conditions.

While there are certain advantages to be gained by the drainage of some aseptic wounds, excellent results are obtained in the majority of cases without resorting to drainage. When it is remembered that in an aseptic wound, in which no antiseptic fluids have been used, there is in a large majority of cases but little oozing, and also that healthy tissues can take care of a large amount of extravasated blood and lymph, the necessity of drainage of clean wounds will appear pressing in only a few cases. He therefore limits drainage among the clean cases to the following varieties: (1) In those cases where there has been much traumatism to the tissues and where large areas of lymphatic vessels have been opened oozing may be expected, and it seems desirable to prevent the collection of such fluid in some dependent part of the wound. (2) where there remain at the termination of the operation so-called dead spaces which cannot be obliterated by deep sutures or other means. These are apt to act as receptacles for any serum or lymph which may escape from the lacerated vessels and which might then furnish a culture medium for some of the bacteria which may be found in almost any aseptic wound. How long should the drain be left in the wound? In his opinion, twenty-four hours is sufficiently long in almost all cases for the following reasons: (a) If the wound is aseptic, all oozing will have practicaly ceased by this time. (b) If any dead spaces had resulted from the dissection, the tissues will have had ample time to adapt themselves to each other and the cavities will be found nearly obliterated. (c) After twenty-four hours the drain frequently ceases to act as such, the meshes of the gauze being filled with coagulated lymph serum, etc., or, if tubular, the lumen will be frequently found obstructed in a similar manner. The opening in the wound is thus plugged and the drain worse than useless. (d) If removed at the end of twenty-four hours, it will be almost never found that infection has traveled along the path of the drain, an accident likely to occur if the drain is left undisturbed for a much longer period.

In the second class, namely, infected wounds and those made to relieve a septic focus, drainage is demanded almost without exception. Drainage of abscess, empyemas, suppurating joints, etc., is effected in the location which gives the best possible escape to the secretions. To summarize, he uses drainage in the following varieties of cases: (1) When pus is found in the free peritoneal cavity, as in acute diffuse suppurative peritonitis. (2) When there is localized pus formation in the free peritoneal cavity, such focus being walled in by the viscera and adhesions uniting the adjacent viscera. This includes cases of appendicular abscess and pelvic abscesses from pus-tubes, ovaries, etc. When operation is done to remove a collection of pus within a hollow viscus, as a pyosalpinx, or an appendix distended, but not yet ruptured, it is a rule to close the abdominal cavity without drainage unless it has become contaminated by pus by the rupture of the viscus which is undergoing removal.

Irrigating Fluids in Abdominal Cavity.—This subject was discussed by Dr. J. B. Murphy, who said that the purpose of irrigation is, first, to remove foreign material from the abdominal cavity; second, to dilute the poisons in this cavity; third, to prevent adhesions, and, fourth, to prevent or stop shock. For the prevention of shock, irrigation is of little or no value More effective means are now found in intravenous saline injections. The primary purpose of abdominal irrigation is to remove aseptic materials from the abdomen, post-operative, that is, blood, fragments of tissue, cyst contents, serum, etc. Blood-clots can be removed with dry aseptic sponges better than by irrigating fluids.

THERAPEUTIC HINTS.

For Membranous Scarlatinal Angina.—

℞ Cresoti ..... ℥ xvi
Thymol ..... gr. xvi
Spts. Camphoræ ..... ℥ iss
Ol. Terebinth ..... ℥ iss

M. Sig. External use.

This can be used either for spraying the pharynx and nasal cavities for 10-20 seconds every two hours, or for inhalation from a flask provided with two glass tubes. In twenty-four hours the mucous membrane will appear more normal and the false membrane will begin to loosen, evidencing an improvement which progresses steadily. This treatment does not at all preclude or interfere with the use of antiseptic gargles or lavage of the nose or throat or with internal medication.—*Malinowskly.*

ORIGINAL ARTICLES.

THE RELATION OF THE CLINICAL LABORATORY TO MODERN SURGERY.[1]

BY WILLIS G. MACDONALD, M.D.,
OF ALBANY, NEW YORK.

THERE is an impression current in the minds of many that the responsibility of the modern surgeon is not as great as that of his predecessor. A little reflection will show, however, that that very desirable condition does not exist. The loss of a patient from septic infection after an uncomplicated compound fracture will not be as readily forgiven to-day as it was thirty years ago; nor would eleven deaths from sepsis after seventeen amputations done in a year be viewed with complacency either by hospital boards, the profession or the people. Yet surgeons in the not-too-remote past maintained themselves in high positions with so serious mortalities for which they were not held accountable.

Modern surgery is largely a surgery of election. Operations are undertaken because of the safety of the procedure on patients who might live several years without surgical intervention. The loss of a patient from sepsis after a hysterectomy for small fibroid tumor, or after an interval operation for appendicitis is too deplorable to contemplate. These operations were not done by our predecessors and they assumed no responsibility in the matter.

Pasteur studied the organisms found in the secretion of wounds and cultivated them, but it remained for Koch to so develop bacteriological technic that through improved methods he was able to differentiate the micro-organisms of the infectious diseases. Bacteriological investigation of other sources of septic infection than the air were now pursued with great enthusiasm and their well-nigh universal distribution found. No one appreciated more fully than Mr. Lister the importance of these discoveries, and at the close of an address by Pasteur, at the Seventh International Medical Congress, he took occasion to congratulate both Pasteur and Koch on having established beyond dispute, through laboratory research, the first principles of modern surgery.

Schimmelbusche, appreciating the importance of this form of investigation, organized a bacteriological laboratory as an adjunct to the surgical clinic and was among the first to undertake routine bacteriological provings in general surgical work. The results of his investigation led to the development of the aseptic technic of Von Bergmann in contradistinction to the antiseptic technic of Lister. It was my privilege to assist Schimmelbusch in his early efforts and the detail arranged by him will now serve for all necessary requirements.

The continued provings, by cultural methods, of our surgical technic is a first requisite for work of a high standard. However much surgical technic of different surgeons may differ in detail, it has its primary basis in the laboratory. To establish a given method of sterilization as effectual by a single series of cultural provings is not sufficient. It will be found that unless a culture is likely to be taken at any time from any package of dressings, sutures or other materials, variations in the methods of sterilization may be made by the nurse or assistant. It has been my practise to take at irregular intervals, and without notice, provings from the operating-room, from the dressings, sutures, ligatures, towels, instruments, water, hands of the operator and assistant and skin of the patient. In aseptic cases these cultures are taken at the end of the operation instead of the beginning. If, from any portion of the hospital an unusual number of failures present, the head-nurse is informed or an investigation inaugurated. In addition, cultures are taken from the nurse's hands having charge of the preparation of the patient. The professional pride shown by the nurses in the work is very gratifying. While developing colonies occasionally adds a sorrow, yet it is soon dissipated by subsequent successes. In this way a high standard is established and a proper *esprit de corps* maintained. Nor is this all the advantage acquired. We hope finally to be able to establish a method of skin disinfection, which is uniformly effectual with the minimum discomfort to the patient.

The uniform disinfection of the hands of the surgeon and his assistants by any method is settled negatively in my mind. Out of several hundred cultures taken, a sufficient number developed colonies under the most unexpected circumstances to demonstrate the necessity of rubber gloves in order to exclude a serious menace to the patient. They are now worn at all operations regardless of their character and in the final preparation of the field of operation. All dressing of septic wounds is made with gloves. It is only proper in this relation to refer to the fact that catgut for sutures and ligatures should never be employed without cultural provings of each portion after fresh preparation.

The whole fabric of surgical technic depends for its efficiency upon the routine laboratory investigation and upon nothing else. The utility of the laboratory in arresting what may be called

[1] Abstract of the President's Anniversary Address delivered at the ninety-fourth annual meeting of the Medical Society of the State of New York, held at Albany, January 30, 31, and February 1, 1900.

septic storms is unquestionable. Occasionally a series of infected cases will present themselves, although great care is exercised. This is not an isolated experience, but occurs in many of the best clinics under the most careful surgeons. In my experience it is usually a staphylococcus pyogenes aureus infection of a virulent type. The condition requires a most searching investigation, and that major surgery be made to remain in abeyance until the infection is traced to its source and destroyed.

Nor is the utility of the laboratory ended here. In the investigation of obscure genito-urinary diseases it is most useful. The exclusion of early renal tuberculosis requires all the refinements of modern methods of investigation. The evidence of cover-slip staining, culture and animal inoculation may be required in order to demonstrate or exclude the disease. The further exact methods of diagnosis are frequently sufficient to indicate the necessity for early and successful operative intervention in cases in which under ordinary conditions delay might involve grave danger to the patient.

Delayed shock and fat embolism have been a very present refuge in cases of overwhelming sepsis or intoxication. Delayed shock is not shock—it is either hemorrhage or sepsis; nothing else. All the cases of delayed shock that have come either directly or indirectly under my observation were either confirmed as sepsis or hemorrhage at autopsy or were buried with such unseemly haste that no examination could be made. There can be no doubt that fat embolism does occasionally occur, but it is rare. Frequently obscure general infections not associated with pronounced symptoms terminate fatally very suddenly. It has been my misfortune to see a fatal post-typhoid infection after an operation for extra-uterine pregnancy in a patient already convalescent from the fever.

The bacillus pyocyaneus is capable of originating a general septic process, the symptoms of which are not sufficiently uniform to permit of general classification. Cultural examination of the blood has frequently demonstrated the condition. In other obscure septic processes, more especially those with no demonstrable points from which the infection was introduced, cultures taken from the blood will demonstrate the nature of attending joint involvement. Information of much prognostic value is often obtained in this manner. Patients do not recover when there is either a general streptococcus or staphylococcus infection, but may when the infectious bacterium is the bacillus pyocyaneus or the bacillus coli.

Serotherapy as an agent for the relief of surgical sepsis has been disappointing. The antistreptococcus serum of Marmoreck has not justified the earlier claims of its discoverer. However, we have seen enough to encourage us in the perfection of the serum. It can hardly be expected to cure mixed or unusual varieties of streptococcus infections. As a preliminary to further study of antistreptococcus serums, a thorough re-investigation of the streptococcus order is essential There are always many facts observed that indicate that there are many subvarieties of streptococcus presenting independent clinical characteristics. Varieties must be isolated and so combined in culture that the resulting serum is antidotal to the kind found at the seat of the infection. The utility of the serum treatment of diphtheria is so established that there can be no doubt but that others will be discovered equally effective. The tetanus serum certainly possesses antidotal properties. When given in suitable quantities, I have invariably seen improvement follow its use and in one case I believe it was a life-saving agent. In this latter case nearly five hundred cubic centimeters of serum were given in two doses. In my experience the prescribed dose is far below the quantity required. Enough results have been obtained, however, to justify further and most painstaking investigation. Serotherapy must, however, be employed in conjunction with laboratory methods if it is to occupy an important position in the treatment of surgical infections.

The discovery of actinomycosis and its cause, the ray fungus, has attracted the investigation of other orders of vegetable life closely allied to bacteria. Some of the yeasts and moulds are pathogenic to man. The investigation of the oriental boil, madura foot and allied conditions has been fruitful and allows us to hope that the next decade will demonstrate beyond dispute etiology of other obscure problems of surgery.

The apparent increase of cancer has attracted universal attention and many indefatigable workers are now re-investigating the disease. Already much that is promising has been determined. At this meeting a report will be presented embodying all the latest discoveries in this very important department of endeavor. The task may appear beyond our powers. It will involve a radical departure from the old and require new methods of investigation.

The laboratory has other tasks to perform besides those already considered. The study of the secretory and excretory functions of the body has an importance hardly to be overestimated. Unfortunately suppression of urine and intestinal paralysis play an important rôle in surgical mortality.

The examination of urine requires further investigation than is found in color, reaction, specific gravity, sediment, albumin and sugar tests. The total elimination of solids by the kidneys during twenty-four hours is an important problem where anesthesia is involved. The presence of pepton, indol, indican and other albuminoid principles are an evidence of disordered metabolism due to disturbances of the normal functions of the liver and intestines. The wisdom of undertaking any serious surgical operation without the fullest inquiry into the condition of the intestinal tube and kidneys is doubtful. Frequently this involves delay, but I have never regretted a few days' waiting. On the contrary, some of my

greatest misfortunes have come through undue haste at the solicitation of the patient and attending physician.

The routine examination of the blood is not less essential than either chemical or bacteriological investigations. For example, the approximate estimate by von Fleischl's method of the hemoglobin yields very important information after severe concealed hemorrhage, such as occurs in ectopic gestation, rupture of aortic aneurism, or internal hemorrhage due to the rupture of a kidney, the liver or spleen. Kickvlicz has established a rule never to operate when the hemoglobin is under thirty per cent. It occurs to me that such a rule is open to many objections, yet the estimate is none the less valuable as an indication for conserving all the blood possible during the operation.

Bierfreund has carefully examined and tabulated the results of his investigations of the hemoglobin in a number of cases of malignant disease. It has been found in all of them that the hemoglobin is far below normal, that operations are associated with a very considerable loss and that the hemoglobin in the blood never again rises to a normal point, even months after the operation is completed and the patient's condition materially improved. This is a very important discovery and should lend material assistance in deciding for or against the propriety of operating in advanced malignant diseases.

The question of rigors arising before or after operation is an important one. In the years gone by, very frequently a chill after an operation was attributed to a prior malarial affection or to pure nervousness. It is always a matter of first importance to decide this matter at once by exclusion. The so-called nervous chill, concerning which a great amount of skepticism may exist, is not associated with the presence of the plasmodium malariæ or pronounced leucocytosis. The septic chill on the other hand is not associated with the plasmodium malariæ in the blood. This fact was of considerable comfort to me in my late service in the army. It was my fortune to have a considerable number of the wounded after the battle of Santiago placed in my care. A number of these soldiers also suffered from malaria, and it frequently required the microscopic examination of the blood to determine whether the rigors were due to septic infection or malarial poisoning. This was particularly more interesting to me because the malaria from which the men suffered presented no very uniform or regular type.

The surgeon is frequently called upon to determine the propriety of operating upon tumors in the neighborhood of the spleen, the differential diagnosis of which is frequently attended with many difficulties. The importance of excluding myelogenous leukemia is very great. To make an exploratory incision, to find a leukemic spleen is quite inexcusable in modern surgery because the operator has not availed himself of all the methods of diagnosis. This is equally true in cases of lymphatic leukemia. It is a great misfortune for a patient to have one or two groups of leukemic glands extirpated. The blood condition will never recover from the necessary hemorrhage produced by the operation and the patient's life will be correspondingly shortened by surgical intervention. On the other hand, a differential blood count will furnish indication for the removal of glandular sarcoma and of the lymphosarcomatous nodes of Hodgkins disease. There is no method by which the surgeon can determine the precise nature of the difficulty which confronts him without recourse to blood analysis.

A careful estimate of the degree of leucocytosis frequently gives an important indication for an attack of obscure intra-abdominal conditions. It is of material advantage in deciding whether in a given case you have hydronephrosis, floating kidney, impacted cecum, a distended gall-bladder, typhoid fever or appendicitis. An increasing leucocytosis when the leucocytes present edult types, or the so-called polynuclears, is always an indication for operation in appendicitis. In obscure intra-abdominal conditions, with evidences of intestinal obstruction, which may be either malignant, simple, obstructive or inflammatory, a careful blood count is frequently of advantage. If under such circumstances the blood is found normal, non-inflammatory obstruction is reasonably assured. If, on the other hand, a considerable leucocytosis exists, say of 18,000 or more, together with an increase of fibrin in the blood, an inflammatory cause may be suspected. Still again, if together with the leucocytosis, some distortion in the form of the red blood-corpuscles exists, together with reduced hemoglobin and a small amount of pus and mucus in the feces, the diagnosis of malignancy is extremely probable. On occasion the differentiation of neuralgias, gall-stone and renal colic is extremely important. When unattended by inflammatory conditions, it will be found that under such conditions the blood is normal, or at least is not associated with sufficient change to indicate a specific pathological condition.

Time does not afford the opportunity of indicating, except in this very general way, the usefulness and extent to which this method of clinical investigation may be carried. It certainly opened up a new, large, very promising and very useful field of investigation, one, by means of which, we can still further hope to improve the methods of modern surgery. All of these methods of investigation which I have presented to you require a vast amount of time for their performance. They form one of the best reasons why modern surgery is best done in hospitals which now afford every facility for clinical investigation. The amount of technical requirements demanded of the modern surgeon are far different from those required of his immediate predecessor. Modern surgery is not an art to be assumed at once. It is a science which requires infinite painstaking, conscientious labor, and an amount of technical training not to be attained in

any post-graduate course of six months' duration in any school with which I am familiar.

There is an oft repeated formula that all surgeons should at least have five years' experience in the general practise of medicine before entering upon the practise of surgery. Nearly all the older surgeons have to an extent continued such a general practise throughout their careers. The demands of modern surgery will not permit of such a course. The recent medical graduate who determines upon a surgical career will perfect himself far better by a two years' service as a hospital intern in a well regulated hospital, taking all the services in course. This will afford him the opportunity of perfecting himself in clinical diagnosis including the usual pathological, urinary, blood and microscopic examinations. It will require his entire time to develop any important degree of proficiency in these departments. The two subsequent years may be profitably spent in laboratories for physiological chemistry, general and comparative pathology, bacteriology, anatomy and experimental surgery. These courses will of necessity be taken at large hospitals or universities where abundant material is offered for investigation. During this time his bedside experience will be necessarily limited but the advantages of an out-door service may be secured. He is now in position to assume an assistantship in the operating room of the surgical clinic and to begin the actual life work, and at the conclusion of another year is ready to assume the responsibilities of operative surgery for himself.

Such a course of post-graduate study faithfully pursued will give advantages that are inestimable. The highest order of work demands all these attainments. The modern surgeon must be equally at home at the bedside, in the clinic and in the laboratory. He must be able to direct if not conduct each department. They are dependent each part upon the other and require equal cultivation in order that the symmetry of the whole may be maintained.

PROPHYLAXIS IN GYNECOLOGY.[1]

By HENRY C. COE, M.D.,
OF NEW YORK;
PROFESSOR OF GYNECOLOGY IN CORNELL UNIVERSITY MEDICAL SCHOOL; VISITING GYNECOLOGIST TO BELLEVUE HOSPITAL.

AT this time, when the importance of preventive medicine is so keenly appreciated, less attention has been paid to this subject in connection with gynecology than might be expected, in view of the enormous strides which have been made in this department during the past ten years.

The question often suggests itself to the unprejudiced observer, whether the surgical activity displayed by modern gynecologists is deserving of unqualified approbation. The writer has frequently, in conversation with some of the older members of the profession, been asked why it is that the majority of gynecological cases are now regarded as purely surgical; and, considering the great ingenuity displayed in the invention of new operations, why more time has not been devoted to an investigation of the best methods of preventing many of the pathological conditions within the pelvis. This question has suggested itself to the laity also. Every obstetrician is constantly asked by the sturdy mothers of a former generation why it is that the young women of the present day not only find parturition such a terrible ordeal, but after recovery from what may be regarded as perfectly normal labors, become subjects for the gynecologist, and are obliged to submit to reparative operations before they regain in a measure their former health. This admitted fact is really a confession of our own limitations. An old and estimable teacher and leader in our art stated several years ago that at least fifty per cent. of his patients were furnished to him by the obstetrician. He might have added at that time that twenty-five per cent. more represented the result of neglect on the part of parents and family physicians. The subject of the etiology of pelvic diseases is an old one. It is thoroughly discussed in the introductory chapters of every text-book. It is the first point which is impressed upon us as students. We are all familiar with the details, and yet the fact that there seems to be an increase rather than a diminution in the number of gynecological cases would seem to show that a proper application has not been made of observations which date back to the father of medicine himself. This is a subject which possesses even more interest for the general practitioner than for the specialist, since the former is in a position to prevent many of the ills which the latter is called upon to treat. I am glad that it has been brought before this society, because I feel that you have been satiated with surgical statistics and descriptions of operations. Brilliant as the results have been, I think you will agree with me that before many years have elapsed there will be a reaction against the prevailing notion that gynecology is synonymous with surgery.

The growth of preventive medicine has gone hand in hand with that of pathology and bacteriology, and it is only by clearly understanding the occult causes of disease that we have learned, as yet imperfectly, to prevent its development. The imagination can dimly picture the advances which may be made in the new century. Gynecology has not been behind other branches of medicine in regard to the intelligent application of pathological facts to surgical technic, but in the matter of prevention we are still open to criticism. Thanks to the improved system of medical instruction, the general profession is able to grasp clearly the truth that facts and not theories must underlie every permanent system of teaching. The time has passed when any teacher can expect his students to accept without criticism a theory which he has carefully elaborated in his library. They now believe only what they can see.

[1] Read at the ninety-fourth annual meeting of the New York State Medical Society, held at Albany, January 30, 31, and February 1, 1900.

It is the purpose of the present discussion to present in a practical way the main facts of prophylaxis as applied to diseases of women. The part assigned to me is to introduce the subject by indicating in a general way the topics to be treated by the speakers who will follow.

It is a trite saying that the general practitioner makes the best specialist. Certainly a man who has spent several years in general practise is best qualified to take a fair and broad-minded view of a special subject. It is the well-known tendency of specialists to attach undue importance to single symptoms and, in their anxiety to discover some lesion of the organs in which they are especially interested, to lose sight of the intimate relation between those and the entire body. This is the reproach which rests especially upon gynecologists. For example, it would seem almost self-evident that retroversion of the uterus in a patient with general muscular atony, flabby abdominal walls, relaxed pelvic floor, and displaced abdominal viscera, is but a single indication of a general faulty condition. Yet it is only within the past few years that the condition known as enteroptosis has been generally recognized, and even now many gynecologists disregard Kellogg's dictum that the cure of retrodisplacement is only the first step in a course of treatment intended to restore the general muscular tone. Again, the phenomena exhibited by many patients, especially pains over certain well-known regions, are often erroneously attributed to reflex disturbances arising from a prolapsed ovary, or a minor lesion such as a lacerated cervix, when they are really an expression of a general, rather than a local trouble. The subject of reflex neuroses has been an inexhaustible mine to gynecologists in the past, but, to continue the metaphor, it has been pretty thoroughly worked out. There are evident signs of a revolution on the part of the general practitioner against this tendency of specialists to extend the boundaries of their activity.

A proper comprehension of the causes of pelvic disease embraces an accurate knowledge of the normal anatomy and physiology of the pelvic organs and a study of their development from infancy to puberty, of the various sources of infection from without, and of morbid processes within. The attempt to divorce obstetrics from gynecology has often been made, but it is now clearly recognized that gynecic and obstetric surgery should go hand in hand. The best gynecologist, other things being equal, will be the best obstetrician, and *vice versa*. Consequently, a thorough acquaintance with obstetrical complications and accidents is indispensable for him who aims not only to carry his patient safely through the immediate dangers of parturition, but to discharge her at the end of the puerperal month as well as she was before. The study of that much-neglected subject, the climacteric, which receives so little attention in modern textbooks and lectures, is indispensable. When we add to this a knowledge of the origin and development of malignant diseases, we have indicated, although only superficially, the range of subjects with which it is necessary to be familiar in order to understand the causes and prevention of pelvic disease.

It is hardly necessary to call your attention to the vulnerability of the female pelvic organs, since this is self-evident. Most of the former dangers which attended gynecological treatment, whether operative of non-operative, have been eliminated by the general observance of aseptic technic. But some still remain, and will continue to menace the health of women until some future age shall have discovered more efficient means of prevention than we now possess.

It is a hopeful sign of the progress of the times that the importance of preparing young girls for their duties and responsibilities is more clearly recognized than ever before. Thanks to the impetus which has been given to athletic sports, we may hope that the future wives and mothers will possess bodies more like those of their vigorous ancestors than the class from which we draw our patients. The perils which beset young married women from gonorrheal infection, pointed out long ago by Noeggerath, have been so strongly accentuated as the result of our thorough familiarity with diseases of the adnexa, gained at the operating-table, that we observe signs of a disposition to apply in this delicate and important question the same preventive measures which we are seeking to enforce in regard to tuberculosis.

Through the general application of the principles of aseptic midwifery the dangers of puerperal sepsis have become so minimized that it is not too much to expect that they may in time be completely eliminated, while we may confidently hope that under our modern system of medical instruction the importance of early operative interference in cases of delayed labor and the immediate repair of lesions of the soft parts will greatly reduce the number of patients who may require secondary operations. Of course, a certain class of pelvic diseases are, and doubtless long will be, unpreventable. It is only by a stretch of the imagination that we can conceive of some future discovery by which the origin and growth of benign neoplasms may be foreseen and prevented.

Malignant disease of the uterus is the *bête noir* of gynecologists, and still remains from a prophylactic standpoint as hopeless as ever. But who can prophesy what the future may have in store? With the inevitable discovery of the cause of cancer will come some way of preventing its development, or, at least, of arresting it in the incipient stage.

I have said that it is to the family physician that the question of prophylaxis is of peculiar interest. It is his privilege to watch the development of the young girl, whom he perhaps assisted into the world, whom he has guided safely through the perils of infancy and childhood to

the period which witnesses the change to womanhood. He, more than any other, is in a position to address to her mother, as well as to herself, words of counsel, to guard her against those numerous indiscretions, harmless in themselves, which are common in careless girlhood. The influence of careful diet, regulation of the bowels, the avoidance of errors in dress, violent exercise, exposure during menstruation—all these factors of disease are more or less within his control. He should see to it that mothers are not only thoroughly instructed themselves, but that they teach their daughters the importance of the sexual organs, the significance of the phenomenon of menstruation, and the future duties which lie before them. The question of marriage is one which is usually regarded purely from a sentimental standpoint. It remains for the medical counselor to teach his patients that it has a physical side as well. While no subject requires more delicate tact, certainly a proper regard for the future welfare of the young woman over whom he has watched so many years must lead him at times to proffer his advice, even when it is unasked. It is difficult to see how a conscientious physician could without a protest allow a young girl with serious uterine or ovarian trouble, with a fibroid tumor, with tuberculosis, or with marked cardiac disease, to enter into the matrimonial state, knowing the perils to which she will be exposed should she become a mother. Certainly here are opportunities in the direction of prophylaxis, the neglect of which is inexcusable.

The question of the prophylaxis of syphilis and gonorrhea in the female is one which, in this country at least, we do not seem at present to be in a position to handle by preventive legislation without encountering vigorous opposition. There is room for considerable difference of opinion as to how far the family physician is justified in endeavoring to prevent the marriage of a young girl unless he is possessed of the most positive evidence that she would be exposed to the danger of syphilitic or gonorrheal infection. Every gynecologist has seen too many sad instances in which men were permitted to marry, being assured by their physicians that they had entirely recovered from disease, when the terrible error was proved in the persons of their innocent companions. This whole subject is one which deserves our most earnest attention. We shall never succeed in eliminating the most serious and far-reaching cause of pelvic disease until we have applied to it the same principles of prevention that we have to other communicable affections.

Allusion has been made to the importance of the menopause in its relation to the etiology of pelvic disease and the slight attention which has been paid to it in lectures and text-books. A proper understanding of this peculiar condition, which borders so closely on the pathological, implies a review of the whole range of medicine as well as a study of mental diseases. Even in our present enlightened age the climacteric is regarded too often as a necessary evil which can neither be averted nor mitigated, and that every woman in passing through it has, so to speak, to take her chances. So familiar a subject as the liability of tissues to undergo malignant degeneration after the period of sexual activity is still woefully neglected, as proved by the records of our hospitals which show that in the majority of cases of incurable carcinoma the initial symptoms were entirely overlooked by the attending physician under the impression that they were physiologic, rather than pathologic.

It would seem to be contrary to the spirit of this discussion to include surgical operations under the head of preventive medicine, yet often the wisest conservatism lies in the repair of injuries, not only because of the present symptoms to which they give rise, but with the view of averting future trouble. As a familiar example we may instance the amputation of a lacerated cervix which might become the seat of carcinoma after the menopause; or the removal of a fibroid tumor, which, although not affecting the patient's health, by reason of its increased growth at the time of the climacteric arouses the suspicion of possible sarcomatous degeneration.

One looks back with mixed feelings of wonder and horror upon the local treatment which was common twenty years ago. Considering the absence of cleanliness, not to speak of asepsis, the almost universal practise of inserting instruments into the uterus and in the office performing curettement, the removal of polypi, and even cutting operations (not to mention the barbarous practise, borrowed from our German *confrères*, of introducing strong caustics into the uterine cavity), the only wonder is that any woman escaped an attack of peritonitis. I venture to say that there are many excellent practitioners at the present day who regard the application of aseptic principles to ordinary office manipulations as quite unnecessary. So serious were the results attending the use of tents in pre-aseptic days that they have been largely abandoned. This is to be deplored, since, when properly employed, they are an invaluable aid to the diagnosis and treatment of certain intra-uterine conditions. Doubtless the true reason why certain minor ailments, such as catarrhal conditions of the endometrium, are now rarely aggravated by treatment, as was formerly the case, is that intra-uterine medication has been largely abandoned in favor of curettement under anesthesia. The fact that the attempt to replace adherent organs by forcible manipulation has been relegated to the heroic age of treatment is undoubtedly a distinct step in the direction not only of conservatism, but of prophylaxis. It has been so forcibly impressed upon the present generation of medical students that the endometrium is a highly vulnerable surface, that there is little danger that the old crude methods will ever be revived.

The early recognition and treatment of specific

infection, whether gonorrheal or septic, before it has extended beyond the uterus, is another advance in prophylaxis. Many women who in former days would have been treated by the old routine method of hot douches and the free use of opium, and if they recovered would have been permanently crippled through the extension of the infection to the tubes and peritoneum, are saved from this fate by early curettement. The whole trend of modern pelvic surgery is conservative, and what is conservatism but prophylaxis, the prevention of the manifold physical and mental disturbances with which we used to be so familiar when ovaries were indiscriminately removed on the slightest provocation? The recognition of the fact that the persistence of the ovarian function is necessary not only to favor conception, but by reason of its influence upon the entire organism, has gone far to remove the reproach which rested upon gynecologists. It may be said in general that we understand now more clearly than ever before the importance of the warning *nil nocere*.

In outlining thus briefly and superficially a field which will be covered by the readers who will elaborate each branch of this subject, I have been necessarily limited by the desire not to anticipate the views which they will develop in detail. As I stated at the outset, this subject must appeal to every practitioner of medicine. Whether he approves or disapproves of the surgical activity of the specialist, he will find ample opportunity to apply the principles of prophylaxis in his daily work.

We hear a great deal about the future woman. Her mental development does not concern us as physicians, but with regard to her physical improvement, her more perfect capability to discharge her duties as a wife and mother, it cannot be denied that an important duty devolves upon us. Under the complex conditions which affect her we cannot expect that she will develop the same robust physique and power of resistance enjoyed by her sturdy ancestors unless she is taught to recognize and to avoid those influences which threaten to undermine her health. The strain of mind and body necessary to meet the demands of modern society are so great that only the most careful training during girlhood and the most intelligent care after marriage can offset them. This is the province of the family physician, and he can have no nobler work. It will be fortunate if, as many believe, through a process of evolution, the family physician is destined to become extinct. The specialist can never take his place.

First Aid to the Injured.—The New York Society for Instruction in First Aid reports that since its establishment in 1882, 11,929 persons have received instruction, of whom 7188 passed the examination and received diplomas. Among these 800 firemen have received instruction, and all policemen in the probationary school take the course.

THE ETIOLOGY AND PREVENTION OF UTERINE DISEASE BEFORE AND DURING PUBERTY.[1]

By W. GILL WYLIE, M.D.,
of New York.

The etiology and prevention of uterine diseases is a subject which has interested me for many years. It has, in my opinion, been much neglected by gynecologists, although recently I have noticed that it is commencing to assume more prominence in connection with the broader subject of the prevention of diseases in general. I have always been interested in this phase of gynecological work. During the earlier years of my medical education I became interested in the study of diseases of women, and subsequently, during my service as an interne at Bellevue and the Woman's Hospital, where I studied gynecology under Emmet, Thomas and Peaslee, my inclination towards this speciality was naturally strengthened. As far back as 1882 I published a paper in the *American Journal of Obstetrics*, January, 1882, entitled "Observations on Lacerations of the Cervix Uteri," in which I referred at length to the etiology of this condition. In a paper on "Anteflexion of the Uterus; Its Etiology and Associated Pathological Conditions," published in the *American Journal of Obstetrics*, September, 1883, I again brought out more fully the fact that imperfect development was the real cause of the pathological conditions usually termed anteflexion of the uterus.

In order to thoroughly understand a disease, we must study etiology. When once you get the scientific facts regarding the etiology of a disease its prevention will be plainly indicated. In the paper first mentioned I called attention for the first time, as far as I know in a direct and practical way, to the fact that imperfect development of the generative organs is a most important factor in the causation of uterine disease. Almost ten years later, in the *Transactions of the American Gynecological Society*, for 1898, I published another paper entitled "The Influence of Imperfect Development of the Generative Organs as a Cause of Disease," in which I enlarged on this subject, and since then my views regarding it have undergone very little change.

Suppose we could take a number of men and women and treat them on the same principle as a horse-breeder treats his animals on a stock-farm. By selecting males and females who are physically well developed we could, in the course of time, produce a body of human beings who would be far superior, physically, to an equal number of human beings born promiscuously. Such a thing, however, is of course out of the question, but I believe that as scientific knowledge advances the physical condition of a man or woman will play a much more important rôle in the selection of a proper husband or wife. Good health and a good temperament in

[1] Read in the discussion on Prophylaxis in Gynecology at the ninety-fourth annual meeting of the New York State Medical Society, held at Albany, January 30, 31, and February 1, 1900.

a woman are more important than mere refinement or education. Even under existing social conditions, the family physician can do much to influence and benefit the unborn child. He can, as I have done, take charge of a delicate woman as soon as she becomes pregnant, and so regulate her diet and exercise and mode of life that her physical condition will be much improved, and this will have a decided influence on the child, even before its birth.

Up to the age of nine or ten years, girls and boys should be treated on the same general principles: they should be allowed the same freedom with proper restrictions as to their food, exercise, etc., and as nearly as practicable kept in good general health. They should not be permitted to overexert themselves mentally, or be subjected to excessive mental excitment by contact with older children. Chorea is a very common manifestation among girls of this age; these patients are usually pale and anemic, and when such a child is brought to me for treatment the first thing I do is to examine the clitoris. It is amazing how many of these patients can be entirely cured of their symptoms by practically circumcising the hood of the clitoris. A boy is rendered nervous and irritable by the presence of a long, tight prepuce and an analogous condition may exist in a girl, although it is perhaps not quite as common or severe, because the penis is a larger organ than the clitoris: still they are homologous, and are influenced in exactly the same way. The secretions underneath the hood of the clitoris may give rise to irritation which will cause the child to rub itself until erotic sensations are produced. I have in mind a child two years old, who in this way became habituated to what might be called a form of masturbation; the child was nervous and fidgety, and her mother informed me that she would not go to sleep at night until she had gone through this process of rubbing herself. I examined her and found a clitoris large enough for a girl of fifteen The hood was adherent and granular and very hyperesthetic. It was removed. I have noticed that girls who are subject to catarrhal troubles in general are the ones most likely to have trouble with the clitoris. The secretions from this organ may drop into the ostium vagina, and if they are septic they may give rise to a very persistent vaginitis much like a gonorrheal infection. By operating on the clitoris you will cure the vaginitis. I remember a girl nine years old who had been treated by a prominent gynecologist for two years for a supposed vaginitis which always returned when the irrigations were stopped. Upon examining the child I found that a dirty, creamy, septic material, which came from underneath the hood of the clitoris, was the cause of the trouble. When the clitoris was freed the vaginal irritation and discharge ceased.

The treatment of these cases is extremely simple. It consists of freeing the clitoris and keeping it free. I do not mean that you are simply to push back the hood of the organ and tell the mother to take care of it; she will not do it. These patients can be permanently relieved by a very simple operation, which was devised by my brother, Dr. Robert H. Wylie. The operation is preferably done under ether, because after injections of cocaine the connective tissue becomes puffed and swollen and interferes with the completion of a neat plastic operation. Briefly, the operation is as follows: The clitoris is covered by a hood, which runs up from the labia minor. This hood is loosened and then divided with a pair of scissors up to the corona of the gland. The incision is made longitudinally, but on account of the tension of the tissues it immediately becomes a transverse cut. Two or more sutures are then put in, one or more on either side of the gland, and the edges of the wound sewed together. This pulls the hood to one side, and the head is exposed all the time. The operation is extremely simple to perform, and the wound can easily be taken care of by anyone.

I now wish to say a few words about girls a little further advanced in years. Between the ages of ten and eighteen years the change from girlhood to womanhood takes place. Anything which affects the general health of a girl between those years unquestionably produces a deleterious effect upon the generative organs if it continues for any length of time. I am perfectly satisfied that for a young girl to develop into a young woman she must have not only a sufficient amount of vitality to use for muscle and brain, and for the performance of the ordinary functions of the body, but she must also have a surplus, a reserve force, so to speak, otherwise the generative organs will surely suffer. The generative organs of a girl nine or ten years old are very much as they were when she was two years old; the circulation in these organs is inactive and their development is slow up to about the age of ten, but from that time on they rapidly develop and this requires a certain amount of vitality over and above what is needed or used up by the other organs. They are the last organs to develop, and, as we know, they are not essential to the life of the individual; a woman can get along very well without them, and if she has not a sufficient amount of vitality, those organs will be the first to suffer. I am sure that diseases of the womb are more common among the better class of women, where intelligence, money and sometimes doctors interfere with the law of survival of the fittest, at least in this country, than in any other. Some European writers, basing their assertion upon the number of gynecologists we have here, have even claimed that most American women must have uterine disease, but this I do not believe. Among the better classes, however, imperfectly developed uteri are very common. The reason for this, I believe, is that in this country the girls, during their developmental stage, are not restrained in their studies, as English girls are, and are thrown more into

company with grown people, their general education and knowledge of the world is greater than young women in other countries. They are sent to school when eight or nine years old, and between that age and seventeen or eighteen are supposed to acquire all the technical knowledge they are to have during life. Our young girls are pushed too hard at school; they do not have sufficient freedom out-of-doors. Their mental condition is developed at the expense of the physical, and during those very years the generative organs suffer most. If we permitted our young girls to lead quiet, healthful lives and would not try to educate them too early to act like grown people they would develop better physically as young women in England and other countries do. After puberty their minds could be better developed than by hard and exciting work during the important period of physical development.

Generative organs which have remained undeveloped or have only partially developed readily become the seat of disease. Catarrhal troubles are apt to attack the organs, because the circulation is imperfect. These patients often suffer from a slight leucorrheal discharge, even before menstruation begins. Then, with the advent of that function, there will be pain, perhaps from the very first menstruation, or coming on soon afterward. This reacts on the general nervous system, digestion and assimilation become impaired, the general health becomes worse and this reacts again on the local condition. These young girls suffer from anemia, from uterine polypi and hyperesthesia of the mucous membrane of the uterus. Suppose such a girl marries: if the uterus has developed sufficiently, she may become pregnant, but if the changes have progressed sufficiently she will probably remain sterile. Suppose pregnancy has taken place, however, and the case progresses to term. You cannot expect such an imperfectly developed organ to dilate as fully and allow the head to pass as readily as would be the case in an organ normally developed. A tear will almost certainly occur followed by its usual train of evils, such as subinvolution, displacements, inability to take exercise, chronic constipation, etc., all arising from the imperfect development of the uterine organs.

Functional Disease of the Ovaries.—In many of these cases not only the uterus, but also the ovaries are imperfectly developed, and the function of ovulation is imperfectly performed. This results in many cases in the production of the so-called "microcystic ovaries," and on this account thousands of women have had their ovaries removed when there was no necessity for it. Such a woman, perhaps, complains of dysmenorrhea; she has dragging-down pains in the pelvis and symptoms of uterine disease; upon examination the surgeon finds that her ovaries, one or both of them, are as large as lemons and may be prolapsed; he tells her that she has disease of the ovaries and removes them. That woman stops menstruating and her whole life is to a certain extent ruined. Such operations are being done every day. Every month I see three or four such cases. Sometimes these operations are done by an eminent surgeon, but more frequently by young men. I recently saw a case where a young surgeon removed both ovaries, which were in this so-called microcystic condition, and the Fallopian tubes were not even enlarged. Any disease which attacks these tubes enlarges them. Any man who removes these tubes where the fibriated extremity is not completely occluded is making a great mistake. I do not know of any disease of the tubes which would justify their removal unless the fibriated extremity is occluded by adhesion, unless it be a new growth. In the case I have just referred to, the patient, a young married woman, was brought to me some months after the operation. She was then having all the symptoms of an abnomal menopause, hot flashes, etc., and the contraction of the atrophied uterus was causing nervous symptoms which were ten times more severe than if the ovaries had never been taken out. That is simply one case of the many where microcystic ovaries have been removed without cause. These operations are now being done very frequently by general surgeons in general hospitals, and I claim that in every instance such castrations are done on insufficient grounds. Women lose their ovaries and men make grave mistakes without really knowing it. To remove a young woman's ovaries simply because they are large would be just as senseless as it would be to remove the stomach because it is distended by gas. There is simply a functional disturbance, and there is no necessity for removing them. Give her proper general and local treatment and these cysts will cease forming, ovulation will become normal and impregnation possible. As for curing dysmenorrhea or excessive uterine hemorrhage by taking out the tubes and ovaries, a method of treatment which is even nowadays taught, that is entirely uncalled for. Dysmenorrhea or any uterine hemorrhage, except from cancer, can be cured usually by simple treatment and without the removal of any organ whatever.

The local examination of young unmarried girls should be avoided, if possible. When such an examination becomes necessary I have made it a rule for many years to make it under ether, and I prepare myself beforehand to perform at the same time any *simple operation* which may be indicated, such as curetting, or the removal of uterine polypi, or freeing the head of the clitoris, as already described. In cases of violent dysmenorrhea, where the patient has become accustomed to take morphine or gin to relieve her pain, I resort to free divulsion of the os and put in a drainage tube for ten days or a longer time. I have examined hundreds of young women under ether so that they remained practically unconscious of the fact. The hymen can be gradually dilated instead of cutting or injuring it, and a few months later no one could tell that it

was ever touched. One intelligent treatment under ether is worth many weeks and months of the usual haphazard methods of treating these patients.

The Habit of Constipation.—Next to overseeing the general health, and the application of the necessary local treatment, perhaps the most important factor is the regulation of the bowels. Women, as a rule, are very negligent in this respect, and young women especially os. Their constipation is due to their sedentary habits, to the fact that they do not drink enough water and perhaps to shyness about visiting the closet when there are men in the household. The movements of the bowels occur at irregular hours, and gradually these girls become habitually constipated. In my opinion, the impaction of feces and accompanying straining at stool is a more important factor in the production of uterine displacements than falls or any form of physical exercise that a woman can take. More good can be done by correcting the habit of constipation or rather preventing its formation than by anything we can do for her during menstruation. Very little is said on this subject in the text-books in spite of the fact that it is such a common and so important a factor in the causation of uterine trouble. If we can educate a woman to properly regulate her bowels we have accomplished a great deal. I regard it as one of the most difficult things which gynecologists have to do.

Dress of Young Girls and Women.—The modern costumes of women, especially among the well-to-do classes, is and has been bad for many generations. It obstructs freedom of action and lessens the good effects of wholesome exercise. Lacing is especially bad. I am sure its bad influence on the lower ribs and certain organs is more or less transmitted from mother to daughter, that is, abnormally small waists, with defective lower ribs and muscles of the chest are more common among those whose parents for generations have worn corsets and the accompanying restraining costumes; and it is largely in this class that we find loose kidneys, prolapsed and dragging stomachs, omentums and intestines and small anteflexed uteri or retroverted imperfectly developed generative organs. Many of this class do not need to lace to have a small waist, for they either inherit it or they have failed to develop to normal proportions these important tissues and organs, by freedom of action and normal, invigorating exercise out of doors, etc., If a girl's general health is kept good and she is allowed or taught to take a normal amount of free exercise and does not wear corsets or restrain by pressure the lower ribs and abdominal muscles, until she is fully developed, say at eighteen or twenty, corsets do little harm without giving great discomfort. Whereas, if worn before development is completed, while the tissues are soft and yielding, the bad effects are induced so gradually that even truthful girls will declare they never lace; for in a large measure they unconsciously restrain and prevent normal development. Therefore, without doubt, many cases of uterine disease would be prevented if women wore costumes that gave the same freedom from restraint to normal action of the whole body as that of the dress of the average man of to-day.

Should a young woman rest during menstruation? I would say yes if rest is indicated by symptoms, such as pain, excessive flowing, dragging sensations when up and about her usual vovations, but normally developed girls in good general health do not have these symptoms and in my opinion are not benefited by rest in bed or their rooms, nor even by confinment to the house during menstruation. Until girls are fairly well developed and the function of menstruation is pretty fully proven to be normal, a certain amount of care should be enforced as to severe or trying exercise or work of any kind. Of course, more care should be given to delicate, imperfectly developed young women, but in my opinion it is wrong to regard normal menstruation in a healthy woman as a sickness and that little good, and sometimes harm, comes from keeping girls indoors under unnecessary restraint. I protest against the use of hot gin and other stimulants for pain during menstruation, and especially against the use of opium, particularly the ready use of the hypodermic injections of morphine at such times. Too much reliance on tonics and drugs merely upsets the digestion and further delays full, normal development and may make local treatment a necessity. In girls under sixteen or seventeen years of age, with rare exceptions, the disorders of menstruation can be cured by freedom from enforced study or indoor life, and mental and emotional excitement, with plenty of good, wholesome food, out-of-door exercise and diversion by contact with children as young or younger that themselves. Laxatives and sometimes partly digested or easily assimilated food, and occasionally iron or some simple tonic, such as olive oil, cod-liver oil may be useful. But to give medicine and keep these patients under the same mental and physical environment certainly does not prevent disease of the generative organs, but rather tends to insure their falling later into the hands of specialists; the frequency of which event in a measure accounts for the craze of all young doctors to take up the specialty of operative gynecology.

PROPHYLAXIS IN GYNECOLOGY: OBSTETRICS.[1]

BY JAMES CLIFTON EDGAR, M.D.,

OF NEW YORK;

PROFESSOR OF OBSTETRICS IN THE CORNELL UNIVERSITY MEDICAL SCHOOL.

WE venture to affirm that a large proportion of cases that apply to the gynecologist for relief of crippled pelvic organs owe their invalid condi-

[1] Read in the discussion on Prophylaxis in Gynecology at the ninety-fourth annual meeting of the New York State Medical Society, held at Albany, January 30, 31 and February 1, 1900.

tion to mismanagement or avoidable accidents of the pregnant, parturient, and lying-in states.

We venture further to affirm that this large class of invalids, who owe their condition to careless and unclean obstetrics, can be greatly reduced, if not practically done away with, and that the remedy is to be found not in the preaching, but in the practise of clean and conservative obstetrics. That a careful attention to prophylaxis on the part of the obstetrician is of value not only in anticipating and warding off many of the dangers of pregnancy, labor and the puerperium, but also in preventing many subsequent disabilities of a gynecological nature, admits of no question. Nowhere more than here does the old maxim, that prevention is better than cure, find truer application. The ground to be covered in any proper consideration of the subject is so large, and the time at our disposal so small, that we must content ourselves with briefly reviewing some of the salient points, especially those which have impressed themselves upon us as being of practical value.

The subject may be conveniently considered under three heads: (1) As it relates to pregnancy; (2) as it relates to labor; (3) as it relates to the puerperium.

(1) *Pregnancy.*—There is relatively little we can do during pregnancy which will have a direct influence in the prevention of subsequent uterine and pelvic trouble. Attention to the general health, however, *e.g.*, the prevention of constipation, the proper treatment of coexisting anemia, moderate exercise in the open air, suitable clothing, especially the avoidance of constriction about the waist, in a word, a good hygiene of pregnancy is undoubtedly of prophylactic importance in two ways:

(*a*) By providing the patient with healthy blood, one of the best of germicides, and thus, perhaps, forestalling or minimizing the effects of septic infection; (*b*) by increasing the muscular and the general nutrition, factors of undoubted importance in the prevention of subsequent subinvolution of the uterus and adnexa.

Every pregnant woman should be impressed with the importance of placing herself under the care of the physician who is to attend her as soon as she shall become aware of her condition. It would be wise to give to such a patient early in gestation some simple directions, either verbal or printed, embracing advice regarding exercise, clothing, diet, care of the bowels, skin, kidneys, breasts, teeth, and the danger signals of approaching complications. There can be little doubt that not only patients, but their advisers, are too prone to consider this as a period of invalidism, and to forget that it is a physiologic process. One of the important results of this view is the neglect of muscular exercise, especially in the higher walks of life where the desire to escape observation and the fears inspired by false views lead to the neglect of even the little exercise, *i.e.*, walking, to which the patient is accustomed, and the consequent weakening of the whole muscular system. Now just the opposite should be the case. The strain imposed upon the muscular system by the requirements of labor is a severe one, and should be forestalled by the cultivation, as far as possible, of muscular strength. Time and space do not permit us to enter into detail nor is it necessary; for, the general principle being appreciated, the individual practitioner may be trusted with its application to the particular case.

In the effort, however, to secure a proper hygiene of pregnancy, we should not forget the danger of overexertion; and this brings us to the consideration of one point which we believe to be of especial and direct prophylactic importance. We refer to the avoidance of everything which increases intrapelvic pressure and resulting pelvic congestion.

An improper or insufficient diet during pregnancy can hardly be considered as a direct factor in the production of uterine disease. Acting, however, to produce a lowered vitality, it is doubtless an indirect factor in the production of subinvolution and the evils which follow. There has as yet been little evidence advanced to show that in cases of normal pregnancy any special kind of diet is of importance, nor is it antecedently probable. A mixed diet sufficient in quantity to meet the often increased appetite of the patient is probably the best. Important modifications of diet are, of course, imperative in threatened albuminuria, vomiting of pregnancy, and other morbid conditions, but these need not be considered here. The studies of Prochownik and others with reference to the prevention of dystocia by a restricted diet, and those of Schenck with regard to the determination of sex by an analogous method are chiefly important from the standpoint of pure obstetrics.

(2) *Labor.*—While in the management of pregnancy we can, as a rule, act only indirectly as far as gynecological prophylaxis is concerned, we can in the management of labor do a great deal which is of positive and immeasurable benefit to the patient in preventing subsequent serious and perhaps life-long disability. And we may subserve brevity and clearness by dividing this part of our subject into three parts, as follows: (*a*) Limiting the duration of labor. (*b*) The prompt surgical treatment of traumatism, the result of labor. (*c*) And most important of all, the observance of strict asepsis.

(*a*) That a labor prolonged beyond the limits of safety is of itself the cause of subsequent local trouble is, of course, well known. This statement is applicable to all kinds of abnormal labor, but perhaps finds its best application in cases in which local sloughing of the maternal parts is caused by prolonged pressure of the fetal head. Vesicovaginal fistula at once suggests itself in this connection. And this brings us to the fact that maternal lesions may be the result not only of the premature or unskilful use of the forceps, but also of undue delay in their use. To lay down exact rules, as some have attempted to do,

as to the time which should be allowed to elapse before the application of the forceps without reference to the individual case, is, of course, wrong. Many other circumstances must guide us here. But it is safe to say that when with good uterine contractions the head remains stationary, the danger of injury to the maternal soft parts becomes an important factor. A similar danger also arises from too prolonged efforts to retard the passage of the head through the vaginal outlet in order to prevent laceration of the perineum. We refer here not only to the dangers arising from prolonged pressure, but also to permanent relaxation of the muscular structures of the pelvic floor with resulting disability.

(*b*) It should be the aim of the obstetrician to leave his patient in at least as good condition as that in which he finds her, and no man should attempt the care of the lying-in patient who does not understand not only the ultimate results of the more common lesions of the genital tract which may accompany the parturient act, but also the methods of their repair. Not long ago when trachelorrhaphy was a very common operation and when the importance of cervical lacerations with reference not only to the etiology of cancer, but of various lesser troubles, the immediate suture of cervical lacerations was advocated in many quarters. With the advent of more correct views, however, the majority of obstetricians do not favor the immediate repair of cervical lacerations except when required by severe hemorrhage. The danger of sepsis is by no means inconsiderable.

The importance of the immediate repair of all lacerations which endanger the muscular structures of the *pelvic floor* is now generally recognized . An external inspection of the parts is by no means sufficient, since a severe laceration involving the levator ani may exist without any external sign. A word of caution is necessary with regard to the details of the operation. Too often the operator simply restores the parts to their former appearance without uniting the torn muscular structures. Nor should the danger of sepsis be forgotten, especially when operating high up in the vagina. There is always a slight risk of infection and many a case of puerperal sepsis has had its origin in a perineorrhaphy done without careful antiseptic precautions.

(*c*) Most important of all in connection with prophylaxis during labor is rigid attention to *asepsis* and antisepsis. The importance of septic infection as a factor in the production of uterine and pelvic disease is too evident to need comment. One fact, however, we desire to emphasize, *viz.*, that what is called antiseptic midwifery, while it has enormously decreased the mortality from puerperal infection, has by no means had a corresponding effect upon the morbidity. We are too prone to consider only mortality in our results and to pass over entirely the question of morbidity. Even to-day the influences upon morbidity, the ultimate consequences of a mild puerperal process, are too apt to pass unrecognized by the obstetrician, and the case passes into the hands of the gynecologist for the cure of chronic uterine and periuterine inflammation, which had its origin in an unnecessary if not careless vaginal examination. We hear much of a lowered mortality, and little or nothing of a reduced morbidity.

(3) *The Puerperium.*—Here, while we can not be so aggressive in our methods since the period of action has passed, there is yet much that may be accomplished in the way of prophylaxis. Perhaps as much in the way of combating old and foolish customs as in the introduction of new ones of our own. The all-important question at this time is: How best can we secure involution in the puerperal state?

It is during the puerperium that we should rivet our attention upon the prevention of subinvolution, and especially in cases following the premature interruption of pregnancy. Were closer attention given to this subject in practise the sequellæ of subinvolution, metritis, endometritis, retrodisplacements and prolapsus would be less frequently met with.

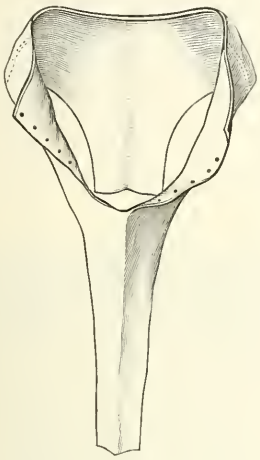
In addition to the familiar means for the prevention of involution, which we cannot do more than hint at here, a routine physical examination of every woman toward the close of the puerperium, and before she passes out of the observation of the obstetrician, is of the greatest value in the detection of slight departures from the normal process of involution, and in drawing our attention to them when amenable to treatment. Were some simple, orderly method of history-keeping of obstetric cases in private practise adhered to, this examination in the puerperium would readily become a routine, and give us valuable records for subsequent reference.

In the puerperium we find two principal factors predisposing to uterine displacement, increased weight of the organ together with relaxation of its supports. It is not strange, then, that the occurrence of displacements at this period should be brought about by causes which at other times would be quite insufficient. Among these we may mention the improper use of the abdominal binder. We believe that the binder, when properly applied, conduces to the patient's comfort, especially by permitting her to assume the lateral position, diminishes the danger from syncope from decreased intra-abdominal pressure, and promotes involution of the abdominal muscles. We would, however, protest against its being applied too tightly, believing that such an application, especially when combined with a prolonged dorsal decubitus, tends to cause posterior displacements of the uterus.

The practise of keeping the patient upon the back for a long period also favors posterior displacement, and we believe that after the first day the lateral position should be advised. This position also favors asepsis by promoting the discharge of lochia from the vagina. For several years past we have taught our nurses and stu-

dents to insist upon a "rotation of the patient" during the whole of the puerperium, meaning by this that the patient's position in bed during a given twenty-four hours shall be equally divided between the dorsal, abdominal, and right and left lateral postures. Many patients insist that they cannot sleep when lying upon their abdomen, or remain for any time in this posture. We have

Fig. 1.



View of Binder Open.

found, however, that with a little practise the habit can be readily acquired. We have counseled the practise of the abdominal posture in early pregnancy in anticipation of the lying-in state and its requirements.

Observation reveals many women who are unable to completely empty the bladder or bowel by the use of the bed-pan, and resulting pelvic congestion and pressure are thus favored. The difficulty could have been avoided had the patient been trained in the use of the bed-pan during pregnancy. Another remedy for incomplete bladder or bowel evacuation and a method which at the same time favors uterine draining is in permitting our patients to either sit upon the vessel placed in the bed, or upon a commode at the side of the bed, early in the puerperium for bladder or bowel evacuation. This has, in the past, been recommended by some in selected cases, and by others in all. In our observation during the past ten years of many thousands of cases confined in the tenements, we have never seen dangerous symptoms result from this practise, and yet the majority of the patients within six or eight hours of their confinement either sat upon a vessel in bed or at the bedside to pass urine.

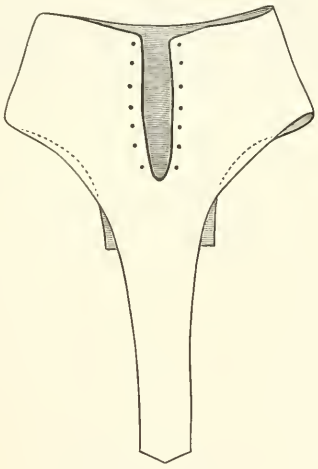
The importance both to mother and child of the proper performance of the function of *lactation* is universally admitted. We would note, however, as bearing especially upon the subject in hand the influence of nursing in favoring uterine contraction and involution, and thus aiding in the prevention of uterine disease.

Getting up too soon and especially too early resumption of household duties are without doubt important factors in the production of displacements and even prolapse, particularly when delivery has been attended by some lesion of the pelvic floor which has been neglected, or improperly or unskilfully treated. Patients should, even after leaving the bed, spend a part of each day in the recumbent posture, and the occurrence of a backache should be regarded as a warning against standing or walking, and especially against any kind of work.

The importance of a routine examination of the pelvic contents and tonicity or sagging of the pelvic floor (levator and muscle) at the completion of the puerperium cannot be overestimated. If this be made a routine, many minor derangements could be at this time corrected which if allowed to remain untreated would by time become aggravated.

Some ten years ago my attention was drawn to cases of undue pelvic floor projection (sagging of the levator ani muscle) and to patients with weak abdominal muscles, especially in women seen in private practise. At that time, at the suggestion of one of my first confinement patients, I first began the use of the pelvic binder to sustain

Fig. 2.

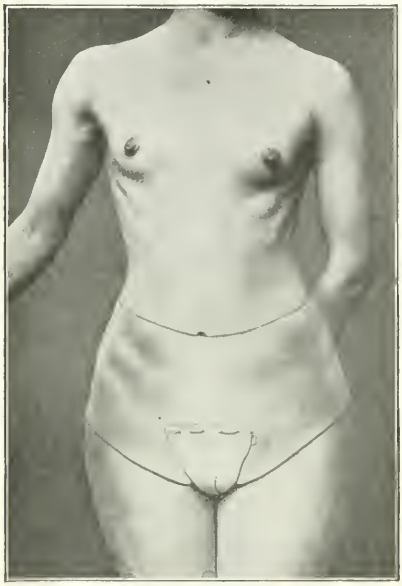


View of Binder Closed.

the pelvic floor and the lower portion of the anterior abdominal wall in selected cases for three months following the puerperium. The results obtained were so satisfactory that I soon used the pelvic binder in all cases. The binder is made of muslin, linen, mull, canton flannel, or

two thicknesses of heavy gauze, and as the illustrations show, is made to encircle the pelvis and lower abdomen at a level with the crests of the ilia, and to support the pelvic floor by means of a strap made of the same material, which passes between the thighs and, tightly drawn, is pinned

Fig. 3.



Binder in Position. Front View.

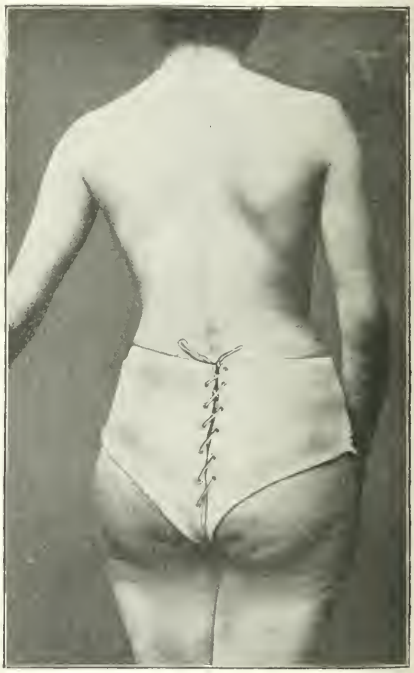
either in front or behind, as is most convenient.

Ordinary corset lacing down the front or back secures a snug fitting of the binder. The pelvic binder when applied, laced, and the perineal band secured, is not unlike in appearance and shape the ordinary swimming trunks worn by bathers. I am accustomed to have half a dozen or a dozen pelvic binders fitted and made in the latter part of the puerperium, and to replace with it the use of the ordinary abdominal binder as soon as the lochia has practically ceased in the third week of the puerperium, and when the patient first commences to sit up in bed or changes from the bed to lounge, and to continue its use for three months from this time.

The results obtained by the use of this pelvic binder have been more than satisfactory. Its benefits have been readily appreciated by my patients themselves, some having used it after as many as three confinements. (1) It prevents or corrects undue sagging of the pelvic floor. This is especially noticeable in cases where, during labor, the levator ani muscle has been subjected to severe or prolonged pressure, as in disproportion between the head and the outlet, in breech presentations, in forceps or craniotomy cases, or prolonged labor near the termination of the second stage from any cause, in severe lacerations with bad union, and in cases where the levator ani is torn and the perineum remains intact. (2) It assists in the ultimate union of severe lacerations of the pelvic floor which have been repaired. (3) It preserves the woman's figure after confinement by its support of the lower anterior abdominal wall and of the pelvic floor. (4) It lessens the danger of displacements of the pelvic contents. (5) It tends to prevent pelvic congestion. (6) It usually adds to the comfort of the woman, giving her a feeling of security and cinal methods of treatment of the puerperium in well-being and allowing her to obtain needed exercise earlier and more freely than otherwise would be the case.

Unless preexisting pelvic disease be present,

Fig. 4.



Binder in Position. View of Back.

with the use of this pelvic support we rarely see the danger signals of pelvic congestion, namely, backache and symptoms of irritable bladder.

What place have drugs and various non-medi- the prevention of subinvolution and subsequent

gynecological conditions? During the past ten years we have experimented with various methods of management of the puerperium, with the object in view of determining, if possible, the best treatment for the prevention of subinvolution and subsequent gynecological conditions. A record blank was adhered to in all cases, and as accurate and careful records as the circumstances permitted were kept, and in a large proportion of the cases the examination upon a given date of the puerperium, and the measuring of the depth of the uterine cavity were made by the writer.

Observations were made as follows: (1) No medication during the puerperium: Primiparæ, 22 cases; multiparæ, 21 cases; total, 43 cases. (2) Strychnine during the puerperium: Primiparæ, 48 cases; multiparæ, 55 cases; total, 103 cases. (3) Strychnine during the last two or three weeks of the pregnancy and during the puerperium: Multiparæ, 30 cases. (4) Ergot (3ii) after completion of the third stage only: Primiparæ, 18 cases; multiparæ, 13 cases; total, 31 cases. (5) Quinine (gr. ii. t.i.d.) during the puerperium: Primiparæ, 22 cases; multiparæ, 23 cases; total 45 cases. (6) Posture in bed, (*a*) mostly dorsal; (*b*) posture equally divided between dorsal, right and left lateral and abdominal. (7) Evacuation of bladder and rectum, by (*a*) catheter and bed-pan, and (*b*) early use of the vessel or commode. (8) Vaginal douches. (*a*) none at all, (*b*) one after the third stage, and (*c*) daily douches during the puerperium.

We are not prepared at this time to give the full results of our observations other than to state the favorable influences of (1) strychnine administered both in the latter part of pregnancy and during the puerperium; (2) the advantages of a "rotation of the puerperium" as regards posture during the lying-in state; and (3) the advantages of an early use of the vessel in bed or the commode at the side of the bed early in the puerperium, in hastening involution, favoring uterine drainage, and in the avoidance of pelvic congestion.

50 East 34th street.

CLINICAL MEMORANDUM.

DIAGNOSIS OF A CASE OF CEREBRAL TUMOR; OPERATION.

By O. M. STEFFENSEN, M.D.,
OF CHICAGO, ILL.

THE patient, a man thirty-two years of age, occupation farmer, had been suffering for three years. The first intimation of any trouble appeared at the death of a relative, which event distressed him considerably. At that time he was conscious of a dizzy sensation, which persisted for one and a half hours, followed by a numbness in the right upper extremity, also complete aphasia, which lasted only a few moments. A slow oscillating movement of the right arm was noticed for eight hours, during which time a severe frontal headache was present. The patient then seemed quite well for one and a half years, when a numb sensation flashed through the right forearm, followed in three hours by a severe frontal headache which subsided ten hours afterwards. The patient again seemed normal for six months. One morning, six flashes of numbness were felt during a period of three hours, followed by frontal headache. During the afternoon the patient gave a cry, passed into a tonic, followed by a clonic, convulsion, and then remained in a stuporous condition for twelve minutes. Unconsciousness prevailed during the spasm. Headache was present for three days following this. Last January vomiting of the projectile type manifested itself and recurred about every two weeks and was accompanied by severe headache in the frontal region. The vomiting persisted five minutes, the headache one to three days.

In July an attack began, as usual, with vomiting on the first day, followed by headache. On the third day lateral nystagmus was observed for five minutes, succeeding which an outward deviation of the right eye was noted. Diplopia was present for three weeks. In the month of August fourteen vomiting spells occurred in one day, the spasms being about one hour apart. Following these the patient passed into a rigid condition lasting twenty-four hours. During this state the eyes and mouth were tightly closed, hands clenched. After this he was able to speak and act; he also declared that he could hear perfectly well during the rigid state. Subsequent attacks consisted of vomiting and headache only. Sight was gradually failing.

Upon examination of the patient partial iridoplegia was found. Fingers could be counted at nine inches in the left visual field, and only at three inches in the right field. A slight external deviation of the right eye could be detected. Choked disc was present. The patellar reflex was present in the left leg, but entirely absent in the right. Considerable movement in the right arm was present during sleep. Agraphia and aphasia were both present, but appeared to be mainly sensory in character inasmuch as the patient was able to repeat words quite well, although to name many objects when shown him was an impossible act. Writing was also possible when the form of a particular letter was described to him, otherwise not. Alexia was a prominent symptom. The appetite was fair, bowels were very sluggish. Urine normal. Mentally the patient presented a very stupid and listless state.

Based on the preceding symptoms and examination, a diagnosis of tumor in the region of the angular gyrus on the left side was made.

On the 25th of November the case was operated on by Dr. L. D. Rogers, and a tumor weighing three ounces, seven inches in circumference, was removed. The growth extended down into the cerebral tissue for a distance of three and a half inches, involving the angular, supramar-

ginal and the base of the first temporosphenoidal gyri. The patient survived two hours after the operation, death resulting from shock and hemorrhage.

MEDICAL PROGRESS.

Insanity and Pelvic Lesions.—A. T. Hobbs (*Am. Jour. of Obstet.*, Jan., 1900) considered the relation between pelvic lesions and insanity and gives some very interesting statistics. Of 800 insane women under observation 220 were examined, and in 188 of these distinct lesions of the pelvic organs were found. There were 371 lesions diagnosticated in the 188 cases. These 220 women were selected for examination as possible cases of pelvic disease, which fact accounts for the great number of lesions found in the cases. Up to date the writer has operated upon 173 of these cases, performing a total of 311 operations, as follows: Curettage, 131; trachelorrhaphy or amputation of the cervix, 53; Alexander's operation, 37; ventrosuspension of the uterus, 13; perineorrhaphy, 27; ovariotomy, 22; abdominal hysterectomy, 14; vaginal hysterectomy, 9; myomectomy, 3, and celiotomy for tubercular peritonitis, 2. The result of this work was an improvement in general health in many cases, and a wonderful improvement in, or a complete restoration of the mental functions. Of these 173 cases operated upon, 73 recovered mentally; 41 improved mentally; in 55 the mental condition was unchanged, and 4 died. Thus 114 were benefited not only physically but mentally by the operative treatment. As to the relative influence of the various lesions in maintaining or causing mental disturbance it was found that (1) after the removal of ovarian or tubal disease in 24 cases, 15 became sane and there was an improvement in 4; (2) after correcting disease of the lining, body, or neck of the uterus in 72 cases, 33 became sane and 14 were improved; (3) correcting retrodisplaced and prolapsed uteri in 47 cases was followed by mental recovery in 17 and improvement in 12; (4) removal of tumors, malignant and benign, in 20 cases was followed by 6 recoveries and 8 improved; (5) repair of injuries to vagina in 10 cases resulted in 2 recoveries and improvement in 3 cases. Thus it is seen that fifty per cent. of the cases of inflammatory utero-ovarian disease operated upon recovered mentally; thirty-six per cent. of utero-ovarian displacements recovered, and twenty-six per cent. of utero-ovarian tumors and vaginal lesions recovered. From this the writer concludes that organic lesions are the most prominent factors among pelvic lesions in causing insanity, and that displaced organs come next and tumors last. Six cases are cited in detail as illustrative of the rapidity of mental convalescence after operations on the pelvic organs. It would seem that diseases of the reproductive organs are marked factors in the etiology of insanity.

Operation for Gastroptosis.—Several operations have been proposed for the treatment of gastroptosis. Gastro-enterostomy and various means of infolding the anterior wall of the stomach by a single row or many rows of sutures have been advocated. Rovsing has hit upon a method of suturing the stomach to the anterior wall of the abdomen at the same time that he puckers it upon itself. He does this by making a median incision, stretching the lips of the wound apart, and passing the needle first through one side of the wound, then with it catching up several points of the anterior wall of the stomach and finally bringing it out through the other side of the abdominal wound. Several sutures passed in this manner will not only shirr up the anterior wall of the stomach, but will hold the whole organ firmly up in its place, and so help it to empty itself. Two of three patients operated upon in this manner recovered their normal weight promptly. The third, whose symptoms had lasted for four years and who had wasted from 140 pounds to less than 60 pounds in weight, improved for a few days after the operation, and then died without reaction seven weeks later, an illustration of the serious character of gastroptosis if allowed to go too long, for no other pathological lesion could be found to account for the death of this patient. (*Arch. f. klin. Chir.*, Vol. 60, p. 812.)

The Female Bladder.—As given in text-books, the measurements and capacity of the female bladder have been ascertained by post-mortem examination, by distention to discomfort by urine or other fluids, and by other inexact methods. G. L. Hunner and I. P. Lyon (*Bull. J. Hopkins Hosp.*, Dec., 1899) have used new methods in their investigations. All their measurements were made upon living women in the knee-chest posture, with the rectum, vagina and bladder distended with air. No discomfort was felt by the women during examination and, therefore, there was no resistance either voluntary or involuntary. The average atmospheric distention capacity of the female bladder, and the actual internal measurements from the internal urethral orifice to certain chosen points on the walls of the bladder were the chief points investigated. The woman was placed in the knee-chest position and the rectum, vagina and bladder were allowed to dilate with air. A close-fitting catheter was then introduced into the bladder and a long, soft rubber tube attached to its external end. The rubber tube was then closed by a clamp and the woman carefully rotated from the knee-chest to the dorsal position. The rubber tube was then put into a deep vessel of water and from below upward into an inverted graduated glass cylinder completely filled with water, and held in this position. The clamp on the rubber tube was then removed and all the air in the bladder expressed by the ordinary gynecological bimanual method. The air thus expressed was collected in the glass cylinder, displacing from

above downward an equal amount of water, and by reading off the amount on the graduated cylinder the exact air capacity of the bladder was obtained. To test whether all the air was thus removed from the bladder it was flushed by means of a double-barreled catheter with boric solution, and any remaining air forced out and collected for measurement. In 25 women the average bladder capacity was found by this method to be 303 c.c., the minimum being 160 c.c. and the maximum 545 c.c. In 22 cases the fluid capacity of the bladder was measured with boric solution, the average being found to be 429.7 c.c., the minimum 210 c.c., and the maximum 840 c.c. The average fluid capacity was, therefore, more than one-third greater than the air capacity. Measurements for both fluid and air capacity were made both with and without anesthesia, and found to be greater with anesthesia than without. The bladders of nulliparæ had a greater capacity for both air and fluid than those of women who had had children. Internal measurements of the bladder distended with air were made, from the internal urethral orifice to (1) the vertex, to (2) the posterior wall, to (3) the left lateral wall, and to (4) the right lateral wall. The average measurements obtained for these four points were: To vertex, 7.14 cm.; to posterior wall, 5.77 cm.; to right lateral wall, 5.92 cm.; to left lateral wall, 6.70 cm. The symmetry of the bladder is shown by the greater average distance to the left lateral wall and is due to the fact that the rectum is found more commonly on the right than on the left in women, and when distended pushes the bladder to the left. The uterus also assists in causing this asymmetry. The average length of the urethra in 17 cases was found to be 3.3 cm., the shortest being 2.7 cm., and the longest 4.2 cm. Some drawings illustrate the methods used.

Orthoform.—A. Luxenburger (*Münch. med. Woch.*, Jan. 9, 1900) reports favorably upon orthoform and thinks the time has come to give it a definite place in the materia medica. Besides its main property, that of a local anesthetic on wounds and ulcers, orthoform possesses a marked power of inhibiting the growth of streptococci, staphylococci and other pyogenic microorganisms. It is not easy to say to what extent true bactericidal activity is present; while the injection of one-twentieth of a c.c. of a pure streptococcus culture to which orthoform had been added ten hours before did not prove fatal to a rabbit, the author is not inclined to regard the drug as strongly antiseptic since a similar culture which had been exposed to the drug but five minutes was followed by the death of the animal on injecting. It was next of interest to ascertain if orthoform could be combined with the usual antiseptics without itself undergoing decomposition. Iodoform, dermatol, europhen and aristol gave negative results, so also calomel, salicylic and carbolic acids, lysol, cresol, lead-water, boric acid and aluminium acetate, ichthyol, turpentine, iodine and copper sulphate. Bismuth subnitrate, potassium permanganate and silver nitrate on the other hand underwent chemical change with orthoform, while with bichloride of mercury and formaldehyde, a precipitation resulted which did not, however, sufficiently damage the orthoform to make it inactive. The anesthetic power of the drug in question appeared promptly after three to eight minutes, no matter what the character, location or size of the wound or ulcer. The pain may not reappear for hours or days, depending somewhat on the local conditions present.

Chloroform Narcosis.—Very interesting contributions have been made to the signs and symptoms appearing on the eve of asphyxia attending chloroform narcosis by Koblanck (*Centralblatt für Gynäcol.*, Jan. 6, 1900). In his article Koblanck states that he has rarely seen mentioned by any one of the numerous writers on the subject any reference whatever to the important athetoid movements of the fingers just previous to impending asphyxia in chloroform anesthesia. These movements are not, however, entirely confined to the fingers but occasionally are seen in the eyelids and eyeball and also in the wrist-joint. This symptom of athetosis is not to be confounded with the voluntary movements seen in the repelling motions made by the patient before full narcosis is obtained; it is only when complete anesthesia has been obtained and all reflexes have vanished that this athetosis is seen. Roblanck lays the greatest possible stress on this symptom, for he says that when it appears, this first sign of danger gives due warning. As yet the pulse and respiration are unchanged and the pupils are either contracted or only moderately wide and, therefore, without reaction. In this state, if more chloroform be given, the well-known signs of asphyxia supervene; if on the other hand the mask is immediately removed, these athetoid movements cease, although the patient is still in complete narcosis and it only very seldom occurs that the respiration and the pulse are depressed. If more attention were paid to this sign of impending asphyxia, it would happen less often for anesthetists to see patients succumb "who had only a moment before breathed well." Another point pregnant with possibilities is the importance attaching to the proper methods of managing a case in which asphyxia has already set in. Koblanck states that the proper method of freeing the air passages is to seize the epiglottis directly with the fingers and draw it forward. Although, very properly, this method is looked upon on all sides as the only proper life-saving one, yet it is curious to notice that in the majority of articles devoted to this subject, not a word is said regarding it. The idea that, in anesthesia of women especially, the pushing forward of the jaw and the drawing out of the tongue with forceps is sufficient to clear the entrance to the trachea is a grievous error and one replete with grave consequences. It is only when

the air-passages are entirely free that the methods for artificial respiration are of any value. It is hoped that these few words will be conducive to the early recognition of impending asphyxia and to the proper method and means of preventing and managing such cases when they occur.

Old Elbow-Joint Dislocations.—Bunge (*Archiv. f. klin. Chir.*, Vol. 60, p. 557) emphasizes the fact that separated portions of bone often prevent reduction in cases of backward dislocation at the elbow. In seventeen cases in which operation was performed, such a fracture was wanting in only three instances. The piece which is broken off is often the epicondyle. The fragment may be the size of a pea or it may be many times as large, including a part of the trochlear surface of the humerus. It may also come from the olecranon or from the coronoid process of the ulna. The use of the X-ray has greatly aided in the location of such fragments, but it is not safe to trust to radiography alone, as often a part or the whole of the fragment does not appear in the radiograph. The commonest situations for the fragment are the anterior and posterior fossæ above the articular surface of the humerus. The presence of such a fragment may prevent reduction, and in case some time has elapsed since the accident, strips of periosteum, which have been torn from their normal situation, may lead to the formation of new bone which will obscure the diagnosis and still further prevent reduction. Bunge advocates one or two long longitudinal incisions made over the condyles of the humerus. The first incision made should be on the outer side of the arm, as in some instances it alone will suffice. These incisions do not expose the joint as well as a transverse incision, but they have the great advantage of preserving intact the apparatus for flexion and extension of the arm. After reduction is accomplished the forearm should be put up at an oblique angle, fully pronated, since supination tends to reproduce the dislocation. In from three to five days, if the wound heals well, the surgeon should begin to make passive motions of flexion and extension in order to secure a movable joint. This plan of treatment will not give a perfect joint in every case, but the results thus far obtained are very satisfactory.

Antitoxin in Diphtheria.—There have been recently a number of reports given in the medical journals adverse to the use of antitoxin in diphtheria. The evidences, which come from the general practitioner, seem to throw some doubt on the value of previous excellent statistics and on the statements of good authority that "the problems concerning diphtheria have been completely solved so far as its practical aspects are concerned." A. Rupp (*N. Y. Med. Jour.*, Jan. 2, 1900) contends that too much dependence has been placed on the value of this antitoxin and that many practitioners have now come to use this method of treatment in order to give themselves "peace of mind" rather than with the expectation of any decided benefit. He further believes that in a large number of true clinical cases of diphtheria no Klebs-Loeffler bacillus can be found and that the etiological relation of this germ to diphtheria has by no means been proven.

Apoplexy of Uterus.—It has been the experience of M. Simmonds (*Münch. med. Woch.*, Jan. 9, 1900) that the post-mortem of every third or fourth woman beyond sixty years of age shows, to a varying intensity, a hemorrhagic infiltration of the uterine walls. Histologically there are all the signs of an infarct in the endometrium and adjacent muscularis; the walls of the arteries are calcareously degenerated and necrotic foci of tissue are present in the surrounding tissues. The color of the blood and the lack of pigment show the lesion to be of recent origin, that is, probably resulting during the death agony. It is probable that some of the severe hemorrhages seen during the climacteric may be of the same origin, and this possibility should be borne in mind when all other etiological factors have been excluded. Hysterectomy would be indicated.

Suture of Bladder.—Golischewsky (*Archiv f. klin. Chir.*, Vol. 60, p. 643) says that an incision in the bladder should be sutured immediately, provided no chronic cystitis is present, nor hypertrophy, and the patient is not a hemophiliac, and the kidneys are not seriously affected. A marked hypertrophy of the bladder wall makes it necessary to apply ligatures to its vessels. These can find their way into the viscus if the wound is closed and give rise to formation of stones. He has practised immediate suture in thirty-five cases. One patient, a marasmic child of three years, died in eighteen hours of anuria. There was a left-sided hydronephrosis and double chronic interstitial nephritis. Another patient who had double hydronephrosis, chronic interstitial nephritis and chronic cystitis, died in four days. In five cases there was a leakage of urine. In two of these the wound in the bladder was opened and allowed to close itself. In the other three a catheter was passed and left in the bladder for some days. The fistulæ closed in from two to ten days. In one case hemorrhage compelled the reopening of the bladder. The remaining twenty-seven patients recovered without accident. These results are a sufficient recommendation of this method of treatment.

Home Treatment for Consumptives.—It is often found necessary or desirable to treat cases of pulmonary tuberculosis at home instead of sending them to specially adapted sanatoria. Several very valuable hints to the general practitioner are given by S. A. Knopf (*Med. Record*, Jan. 27, 1900). Under general hygiene he advises the choice of a large, light and well-ventilated room, made as cheerful as possible, but with simple furniture and that which may be easily cleaned without raising any dust. A tuberculous patient should always sleep alone. The careful disposal

of the sputum and other secretions which may contain the bacilli is especially important and must be urgently insisted on. He recommends the use of the aluminum or other metal spit-cup which may be thoroughly boiled or the Seabury and Johnson paper folded cup, which is burned. Dampened cloths may be used and immediately burned. As far as diet is concerned it is important for the patient to understand that his digestive powers are far greater than his appetite indicates. Milk and eggs are, of course, staple articles, but they must be tastefully prepared and given now and then with sherry or whiskey. Steaks, chops, poultry, roast meats, and fish, together with a liberal supply of vegetables, especially spinach, are to be allowed. Light puddings, fruits and nuts should constitute the desserts. The heartiest meal should come between twelve and two o'clock. Remaining in the open air the greater part of the day is essential to the successful treatment at home and may usually be accomplished by providing a suitable protection around the couch or chair to prevent the wind blowing directly on the patient. Walking exercises should be indulged in, but must be carefully regulated, and not carried to the point where the temperature is elevated thereby. A persisting temperature of 100° F. is a contraindication to exercise. Much good is often obtained from the use of the cold douche in the morning especially when applied to the chest and spine. Prophylaxis is, of course, more valuable than radical treatment and hence the welfare of each member of the family should be carefully guarded and the first indication for treatment met.

Rachitis and Suprarenal Extract.—Peculiar crystals have been found in the medulla of the bones of rachitic children treated with suprarenal extract by Stoeltzner and Salge (*Münch. med. Woch.*, Jan. 9, 1900). They appeared as radially and concentrically striated globules or as thin needles when the sections had been preserved for some time in diluted alcohol. After evaporation of an aqueous solution, crystals similar to spermin were seen, but the exact chemical nature has not yet been settled.

Etiology and Symptomatology of Goiter.—The causation of the different forms of goiter as well as the relationship between the size of the goiter and the local and constitutional symptoms which appear, have long proven stumbling-blocks both to the pathologist and clinician. J. G. Adami (*Practitioner*, Jan., 1900) has reviewed the ordinarily advanced causes and has strongly urged the existence of a close relation between the exophthalmic goiter and the ordinary one. Among the less probable causes are a mountainous life and the geological conformation of the country. Evidence has clearly shown that drinking water has a marked effect on the production of goiters, but what the true cause is can only be surmised. That it is infective has seemed probable in some cases. The symptoms of the ordinary goiter he divides into those due to pressure upon the trachea, esophagus, arteries and veins of the neck and upon several nerves, such as the inferior laryngeal, vagus, sympathetic and cardiac branches. Psychical disturbances also occur, which may take the form of dulness and low mental power similar to cases of myxedema, or they may be those of mental irritation, as found in exophthalmic goiter. He also shows how in the ordinary goiter attacks of tachycardia may occur and various symptoms of mental excitement, either transitory or later becoming more constant and perhaps developing a true case of Graves' disease. Furthermore, he points out those cases which have the symptoms of an exophthalmic goiter without the exophthalmos and without the goiter. The relationship of the pathology of these conditions and the symptoms manifested is extremely novel and interesting. It is believed that the common colloid goiter is preeminently a condition not so much of hyperplasia and overgrowth of the specific thyroid tissue as of retention of the glandular secretion. Thus there may be complete retention with all the symptoms of myxedema, or a localized retention in which event the healthy thyroid performs the functions of the gland and the symptoms due to pressure of the tumor are alone present. Again, the localized disturbance may lead to a retention with the occasional increased absorption or discharge of the retained material, resulting in the paroxysmal attacks of dyspnea, diarrhea, tachycardia, etc. In primary Graves' disease there is an increased activity of the gland with hyperplasia of the tissue without retention or, as in the peculiar cases mentioned above, there may be increased activity without any recognizable enlargement of the organ. Thus the essential cause of Graves' disease differs from that of the ordinary goiter since it results in a nervous or other stimulus leading to an increased activity and secretion. In the simple ordinary goiter the sudden liberation of some of the retained secretion best accounts for the paroxysmal attacks which occur, as well as for the dangerous and sometimes fatal results following the operative handling of the diseased gland.

Prolapse of the Rectum.—Dudloff (*Archiv für klinische Chirurgie*, Vol. 9, pp. 717-811) divides cases of prolapse into three groups, designated as follows: (1) Proplapsus ani; (2) prolapsus recti, prolapsus ani et recti; (3) prolapsus coli invaginati. These three groups are quite distinct in pathogenesis and treatment. The cause of prolapsus ani is obstruction of the circulation, and the condition is essentially a hemorrhoidal one. Proplapse of the anus and rectum, or the rectum alone, includes all layers of this organ. It is really a perineal hernia whose sac is formed by the rectum itself. In the third class are included cases of invagination pure and simple. Resection of the affected portion of the rectum is the operation of choice. It is contraindicated in long invagination of the colon, but is strictly indicated if the prolapse is incarcerated or irreducible. In

certain cases milder measures, such as massage or fixation of the colon, may be tried. If the patient is very weak and cannot withstand narcosis or hemorrhage, ligature may be applied. Colopexy with the formation of an artificial anus is to be rejected. Cauterization is of benefit in cases of prolapse of the anus, or prolapse of the rectum, in children, and as an additional measure in instances in which operation has been only partially successful. Galvanic treatment sometimes succeeds with nervous patients and those who can afford a long course of treatment. Rectopexy, Gersuny's twist, and rings of silver wire are unsuccessful and injurious procedures. In some instances it may be necessary to establish a sacral anus. Prolapse may be due to syphilis, and if so demands antisyphilitic remedies. Before any operative procedure is undertaken the bowels should be thoroughly moved for several days; and for several weeks after the operation the patient should defecate in only a horizontal position.

Laboratory Milk for Infant-feeding.—Laboratory milk is theoretically a perfect substitute for normal human milk, as it is prepared under the best conditions as regards cleanliness, has a fixed alkalinity, definite percentages of fat, sugar, and proteids, and is given in uniform daily quantity. Starr (*Archives of Pediatrics*, Jan., 1900) however, cites fifty-four cases in only three of which could the milk be continued up to the time of beginning a mixed diet; in sixteen the health gradually failed, so that the food was discontinued after from six months to a year; and in the other thirty-five cases acute dietetic disorders, chiefly acute gastritis and scurvy, required its early discontinuance. The reason for this is thought to be the destruction of the natural emulsion by the laboratory methods of separating the fat, this resulting in diminished digestibility of the proteids. A child of ten months, which can take only 1.50 per cent. proteids in laboratory milk will thrive on the following mixture containing 2.97 per cent. proteids: Cream 16 per cent. ʒss, milk ʒss, milk sugar, ʒi, water ʒii, such a mixture retaining the natural emulsion, and being easily prepared and pasteurized at home.

Infantile Convulsions.—A general résumé of eclampsia of infants is given by J. Lange (*Münch. med. Woch.*, Jan. 9, 1900). The condition usually appears suddenly in a previously healthy child, with or without laryngeal spasm, then follows a tonic convulsion and soon clonic contractions, varying in duration from seconds to hours and terminating either in death or in exhaustion and sleep, during which the attack may recur. Consciousness is lost, the pupillary and corneal reflexes are absent, the eyes are widely open and are rolled about; the large fontanelle may bulge, there may be trismus and foam about the mouth. Soon the respiration becomes stertorous and the defective aëration shows itself in cyanosis. The feces and urine may pass involuntarily; wrinkling of the forehead, nystagmus, strabismus and protrusion of the mouth may be observed. The upper extremity is carried in a rather characteristic manner: the arm is pressed toward the trunk, the elbow and wrist are flexed and the fingers pressed over the thumb or more rarely hyperextended. The abdomen is often contracted and meteorism may be present while the feet may be in the pes equinus position. Unless the respiratory muscles are involved the attacks may last for hours and the termination is indicated by a disturbed rhythm in the convulsions, deeper respirations, pallor or flushing of the skin and perspiration. Mental dulness and sleep usually follow, after which the patients are well again but for some slight lassitude and diminished color. Etiologically infantile convulsions must be divided into organic and functional, but probably many of the latter will be found to be organic when a knowledge of the subject becomes more compiete, since as yet the pathological findings have been very unsatisfactory. The exciting causes are legion, if it is remembered that any sensory irritation of the skin or mucous membranes of the respiratory, alimentary or urogenital tract may be followed by an attack, provided the individual is so predisposed. It seems possible that during an attack there are rapid fluctuations of the blood-pressure in the finest brain capillaries and that the irritation, just as in epilepsy, starts from the motor zone, while the explanation of the greater disposition to convulsions in infants is sought for in the non-development of the inhibitory apparatus. An infectious eclampsia, during the onset of acute infectious fevers is also recognized, but whether the convulsions are due to the fever or the bacterial toxins is not quite clear. The chronic infections and constitutional diseases are also prolific causes of the disorder. With reference to alimentary or metabolic auto-intoxications as possible factors the author tested the toxicity of the urine of a number of cases, but could get positive results only in two. Taking all into consideration, it must be conceded that the ultimate cause of infantile eclampsia is as yet shrouded in darkness. It may sometimes be necessary to differentiate it from epilepsy, but this is often impossible. The diagnosis, must, however, be in favor of epilepsy when there is a bad hereditary taint, when the convulsions occur at varying intervals without any ascertainable cause, and when during the interim there are manifest psychical and vasomotor disturbances.

Nasal Alimentation.—Salomon (*Le Progrés Médicale*, Jan. 13, 1900) describes a method of administering liquids, whether as food or remedies, to patients in whom the more usual means are inapplicable. Rectal feeding is often inadequate or impossible; in comatose or delirious patients the use of the stomach-tube is attended with difficulty and in some cases with danger, and even the expedient of reaching the esophagus by means of a catheter passed through the nostril is frequently rendered ineffectual in in-

sane patients who learn to get the end into their mouths and compress it with their teeth. Under such circumstances a maneuvre that he recommends as simple, safe, and certain is, with a teaspoon to pour the fluid directly into the nares. One nostril is plugged with cotton and the other may, if desired, be cocainized, although this is not at all essential. With the patient in the dorsal position, the head being steadied if necessary by an assistant and kept extended; the operator at the beginning of an inspiration lets the contents of the spoon glide into the nasal orifice, when it will be found that, aided by gravity and the inspiratory suction, the fluid trickles over the vault of the pharynx and avoiding the epiglottis excites the swallowing reflex and is carried down the esophagus. Even substances that ordinarily are strongly irritating to the mucous membrane can be easily administered in this way, the explanation probably being that as the epiglottis is not reached reflex spasm is not excited. If the method is to be used for feeding, obviously to save time it is advisable that the solutions used should be as concentrated as possible. It has been in constant use by the author for twenty years and he has never seen any unpleasant consequences.

Herniotomy under Local Anesthesia.—H. Cushing (*Annals of Surgery,* Jan., 1900) presents interesting data on herniotomy under local anesthesia. General anesthesia is still preferred, but there are certain cases in which it would be a source of danger, as in advanced age, chronic bronchitis and emphysema, pulmonary or laryngeal tuberculosis, marked cardiovascular changes, chronic nephritis, and, above all, shock and vomiting in strangulated hernia. Previous to the use of local anesthesia many patients with hernia were discouraged from seeking operative interference because of the immediate danger of the anesthetic. Bull and Coley (*Annals of Surgery,* 1898) regard sixty years of age as, in general, a contraindication to operation. During the past few months at Johns Hopkins Hospital there have been fourteen cases of herniotomy done under local anesthesia on patients ranging from sixty to eighty-four years of age. For strangulated hernia local anesthesia is specially adapted, for, by avoiding the dangers of the general anesthetic, both primary and secondary, one may keep the balance in favor of an organism almost overcome by shock, by toxines from the bowel, by depletion from repeated vomiting and lack of nourishment. Under a local anesthetic, with danger to the patient, the sac may be exposed, the constriction relieved, and the gut treated according to its condition. If it is viable and the patient's general condition warrants it, a radical cure may be done; otherwise the radical cure may be left until a later date. If the gut is not viable the establishment of an intestinal fistula is the safest procedure. This is readily done under the local anesthetic, and intestinal suture is done later, with far less risk. To succeed in major operations with local anesthesia, an accurate knowledge of the course and situation of the nerves to be encountered is essential, since accidental division of an unexpected sensory trunk often overcomes the inhibition to pain and renders complete narcosis necessary. The hernia skin incision divides filaments of the twelfth dorsal and first lumbar nerves above and of the ilio-hypogastric nerve below. Of the deeper nerves, the ilio-inguinal and genital branch of the genitocrural nerves are usually found as one trunk in the deeper part of the canal, and the early cocainization of this after splitting the aponeurosis is perhaps the most important step of the operation. The usual anesthetic result is a complete loss of sensation of the entire scrotal contents, cord, sac, and testicle, and the inner side of Scarpa's triangle. There is no surface anesthesia of the scrotum itself. Sometimes there is sensation left in the lower attachments of the testicle, supplied by the superficial perineal nerve. If the lower border of the internal oblique muscle is to be cut it must first be injected to anesthetize the trunk of the iliohypogastric nerve which is found there. Schleich's solution, No. 2 (cocaine mur., 0.10; morph. mur., .02; sodii chlor., .20; aq. dest., ad 100) was used. It is practically non-toxic and may be sterilized without dissolution. For the undivided nerve-trunks one-half to one per cent. cocaine was used. Preparatory to operation patients of advanced age are kept in bed several days to see if they can endure recumbency, and to train them to void urine in bed. Three-quarters of an hour before operation one-tenth to one-eighth of a grain of morphine is given hypodermatically and repeated shortly before going to the table. The patient is cleansed, the line of incision infiltrated with the cocaine solution and the incision immediately made through the linear wheal, bleeding points clamped and the field kept dry. Only the upper end of the incision is carried down to the aponeurosis, which is opened and the ileohypogastric and inguinal nerves cocainized with one-per-cent. solution. The lower end of the incision may then be painlessly completed. No further use of the anesthetic is needed. The ileo-inguinal and genital nerves should not be damaged because of resulting cremasteric and scrotal paralysis. The remainder of the operation may be completed according to the preference of the operating surgeon. When, in large hernias, the two rings have become concentric and the conjoined tendon therefore absent, Bloodgood (Johns Hopkins Hospital) opens the rectus sheath and transplants the muscle to form a posterior wall to the inguinal canal. No additional cocaine is needed. If, as occasionally happens, the patient begins to feel pain and loses self-control, a few whiffs of chloroform relieve the pain without the loss of consciousness. There have been no "after-pains," and healing has been absolutely unaffected. The advantages of the method are: (1) No post-anesthetic sequelæ; (2) urinary disturbances are less frequent; (3) diet is unchanged; (4) dress-

ings may be applied originally to suit the comfort of the patient; and (5) above all, the dangers of general anesthesia are avoided. Disadvantages: (1) The operation is a little more prolonged and difficult; (2) some pain is inflicted, but this does not compare with the discomforts of recovery from ether anesthesia.

For Infantile Dyspepsia.—Rochkovsky, of Warsaw, recommends the use of peroxid of calcium for this disorder, whether of the variety accompanied by fetid, mucous stools, or that in which the latter are indigested, resembling chopped-up eggs. The remedy is a yellowish powder, insoluble in water, and has a double therapeutic action; it is antacid by reason of its base and antiseptic because of the slow but constant decomposition which it undergoes with the consequent evolution of nascent oxygen. The daily dose is 3 to 10 grains, given in milk; within three to ten days the stools become normal and the disorder is cured.

For Chronic Catarrh.—The chronic catarrhal inflammation seen in smokers, public speakers, in those exposed to an irritating atmosphere, or as an accompaniment of chronic rhinitis can, according to Condié, be cured or greatly modified by systematic massage. He uses a metal instrument which consists of a slender handle bent near its further end to a more or less obtuse angle and terminating in two prongs holding a revolving ball, the surface of which is smoothly polished. The instrument can conveniently be sterilized in the flame. First the posterior wall and then the lateral walls are treated, the ball always being rolled from above downward in the direction of the veins and lymphatics, at first with very light, then with gradually increasing pressure. Cocaine should be used to diminish reflex action until the pharnyx becomes accustomed to the treatment. A slight soreness is the only after-effect observed. Daily treatment is followed by increased activity of circulation and absorption of the interstitial exudate, while the process favors desquamation and regeneration of the epithelium.

For Bronchitis or Pleurisy.—

℞ Ol. Terebinth ..... ʒ iii
Ac. Acetici ..... ʒ v
Ol. Limonis ..... ♏ lxxv
Aq. Rosæ ..... ʒ iiss
Vitell. Ovi..... i.

M. Ft. linimentum. Sig. To be rubbed on the chest.—*Stokes.*

Treatment of Varicella.—The following statements are credited to Gillet: Unless there is secondary infection of the vesicles suppuration will not occur, and to prevent it and possible cicatrization we need only protect them from irritation and injury. Cleansing the body with a solution of boric acid is preferable to immersion in a bath until the vesicles have dried to scabs, and it is a good plan to powder the body with talcum, bismuth, or zinc oxid. Vesicles showing signs of irritation should be painted with a solution of bichlorid in mentholated oil, or covered with carbolated vaseline or some other antiseptic ointment. The nasal passages should be cleansed and the throat gargled with a strong boric acid solution. When scabbing is complete bichlorid or green soap should be used in the baths. Special attention should be paid to the condition of the conjunctivæ, anus, external genitals, and of contiguous surfaces of the skin. In respect to internal treatment we should prescribe purgatives, preferably calomel, soothing drinks, and such as favor diuresis, as weak lemonade, orange juice, etc. The diet should be light, consisting of milk, eggs, and farinaceous foods. The average duration of the quarantine, depending on the disappearance of the scabs, is twenty-five days, after which time the child may return to school.

Uses of Chloroform Water.—According to Pouchet, chloroform water is not only an agreeable adjuvant in sleeping potions and the like, but because of its antiseptic qualities is well adapted for the preservation of alkaloids in solution for hypodermic use. It has an analgesic effect on the gastro-intestinal mucosa and may be looked upon also as a mild intestinal antiseptic. Pouchet gives the following formulæ:

℞ Morphinæ hydrochlor..... gr. ⅙
Aq. chloroformi sat..... ʒi
Aq. aurantii fl..... ʒi
Syr. simpl. ..... ʒss

M. Sig. Take one-half as sleeping potion.

℞ Potassii brom..... 3 ss — 3 i
Aq. chloroformi dil..... ʒ iii
Aq. aurantii fl..... ʒ i
Syr. simpl..... ʒ v.

M. Sig. Dose as directed.

Dilute chloroform water is prepared by mixing the saturated solution with an equal quantity of distilled water.

For Diabetes in Children.—The following formulæ are recommended by Legendre:

1.—

℞ Antipyrini ..... 3 iiss
Glycerini..... ʒ i
Aq. dest..... ʒ v.

M. Sig. One to four teaspoonfuls a day.

2.—

℞ Strychninæ sulph..... gr. 1/10
Sodii arseniat..... gr. ⅕
Codeinæ ..... gr. ii
Quininæ valerianat..... gr. x
Ext. valerianæ..... q. s.

M. Ft. pil. No. xii. Sig. One to six pills a day.

For After-Pains.—

℞ Tinct. viburn. prun. } aa.....3 ii ss.
Tinct. hydrastis... }

M. Sig. Ten drops in a little water every two hours.

Relief is sometimes best obtained by means of rectal medication, as follows:

℞ Chloralhydrate..... 3 ss — 3 i
Yellow of egg..... No. i
Water or milk (warm)..... ʒ ii.

M. Sig. For injection.—*Vicaire.*

SATURDAY, FEBRUARY 3, 1900.

THE NEW YORK STATE MEDICAL SOCIETY.

We publish in this issue a complete report of the annual meeting which came to a close on Thursday last, and also some of the more important papers. The meeting, from the standpoint of scientific work presented, ranks among the foremost in the history of the Society. The president set a worthy example by devoting the anniversary address to the presentation of a thoroughly scientific subject, thus relegating the politics and business of the Society to the respective committees, where they naturally belong. The address was therefore, interesting and instructive, and demonstrates the fact that bacteriology is taking fully as strong a hold on surgery as on general medicine. From the standard of surgical requirements insisted on, and this is the standard not of the future, but of the present and now, it becomes evident that the successful surgeon is no longer a mere mechanical expert, deft of hand and quick in resources, but a thoroughly equipped man of science whose judgments and decisions must be based in each individual case on investigations of far-reaching import. The address, which may be found in this issue, is wholesome reading not only for the ambitious tyro about to launch into the flood of surgical experience, but also for the active surgeon and general practitioner who ventures in where wiser men fear to tread.

No little interest of the meeting was centered upon the question of State sanatoria for consumptives. An effort was made to have the subject presented in all its aspects, as may be seen by the report, and to convince the State legislators of the importance of the undertaking. But the prospect of any legislation upon the subject at this session is very problematical. This is due, however, not so much to lack of interest or of conviction, for the subject was presented most convincingly both at the general meeting in the Assembly Chamber on Tuesday evening and also before the Committee to which the bill has been referred, but to the unusual demands that are now being made upon the exchequer of the State. These have special reference to the canal schemes. It must be admitted also that the unfortunate lack of unanimity in the profession regarding the practical application of the sanatorium experiment gives legislators a loophole for escape. Some are in favor of one large building in the Adirondacks, others advocate numerous small sanatoria in the vicinity of populous centers, and still others advise appropriations for the support of charity patients in private sanatoria already established. The advocates of these various plans should come together and agree upon some one of these recommendations. In this way unanimity of action will be secured and a solid front presented to the Legislature. Whatever plan is adopted the experiment cannot but prove successful, and pave the way for larger and more permanent establishments.

CARE AND TREATMENT OF EPILEPSY.

It is the victim of a hopelessly incurable disease that seeks refuge in the nostrums of quacks; and there is something indescribably pathetic in the way that an epileptic delivers up his dozen or more "sure cures" when he enters upon the new régime of treatment that is in reality his only chance of improvement.

From Germany, France and England, but especially from New York State comes the lesson that education and out-door occupation are the bases of improvement in epilepsy; and often work absolute cure, a result which can be attained in no other way. At Craig Colony, New York epileptic village, medical treatment for

the disease has been practically abandoned, and regular hours for sleep, a simple diet, chiefly vegetarian, baths, exercise, work and instruction have been substituted, with most gratifying results. In epilepsy it is the individual and not the disease that must be treated. It is through improvement in physical, mental, and moral tone that the patient climbs up out of the state of lazy inert, irascible despair, in which his whole condition is that of progressive degeneration, and acquires an active, useful, cheerful habit of life, which in nearly all cases tends toward fewer and fewer attacks. Nothing contributes to this end so rapidly as congenial, healthy employment, especialy that out-of-doors, where the sunshine, fresh air and surroundings of nature draw his mind from himself and his disease.

It is very difficult to provide suitable treatment for an epileptic at home, especially if he be a child. His inability to attend school or church, his sensitiveness regarding his peculiarity, his outburst of temper, his lack of training, all tend to make him a slovenly, unbearable burden to his friends. And yet he is, at most times, capable of work and enjoyment, and in many cases almost as bright intellectually as a normal child. Therefore is it nothing short of crime to confine him in an institution with the insane or the feeble-minded, where it is his positive doom to become like them.

The Hon. William Pryor Letchworth, in his recent work, "Care and Treatment of Epileptics," has reviewed the whole history of failures in past methods of treatment and has outlined the village system, as it at present exists in successful operation at Craig Colony, in the Genesee Valley. There the patients are divided into groups of twenty or thirty, according to their degree of compatibility, or capacity, and live in separate homes. They do their own housework and have recreations according to their tastes. The children live together, and those that are able attend the colony school, where the instruction is pursued along kindergarten lines and where the development of skill in their fingers tends toward the practical side of life. They go to services and concerts in the chapel; give entertainments and enjoy life as other children do. Meanwhile, they are being trained to support themselves, in the event of their cure, or to do their share of the colony work as long as they live there.

The farm and stock of the colony produce under the patients' labor a large proportion of the colony's food, and from the clay-beds they have made brick enough to put up a number of their buildings. Nearly all the daily occupations of any village life, washing, sewing, waiting, cobbling, gardening, street-cleaning, etc., are represented in patients who, if they were normal, would be fitted for such a sphere, but who by reason of their infirmity cannot keep a position in the world of competition. Nurses, educated in the art of training, work with the patients, study their difficiencies and abilities, and fit them into the niche best suited for them; while expert physicians living in the colony direct the individual treatment of each.

The whole plan in its broadest aspects has been a cherished idea of Mr. Letchworth's for years; and as one of the foremost students of philanthropy and sociology in the State, his voice upon the subject combines the tone of authority and experience. His book is not the plea of a dreamer of social reforms, it is a keen, practical, detailed account of how to bring about and accomplish what most people only talk about. To care for the dependent classes, without pauperizing them, and without overtaxing the community, and to care for the hitherto almost uncurable epileptic in such a way that he may be benefited without sedative drugs, but by the skilful appreciation of the laws of nature, is the problem which Mr. Letchworth has solved in his work; and every State in the Union, and every private sanatorium for epileptics in the country, could not do better than study the question from his standpoint.

ECHOES AND NEWS.

NEW YORK.

Military Surgery.—Major Louis A. La Garde, M.D., U. S. A., will deliver a course of lectures on Military Surgery on Saturday mornings, beginning Saturday, February 3d, at 11 o'clock, in the University and Bellevue Hospital Medical College.

Marine Hospital Service Examination.—The board of examiners will meet at 378 Washington street, New York City, Wednesday, February 7, 1900, for the purpose of examining candidates for appointment as assistant-surgeon in the service. Dr. R. H. M. Dawbarn, No. 105 West 74th street, prepares candidates for these examinations and will gladly furnish definite information regarding them.

Health Report.—The Health Department presents the following report of contagious diseases for the week ending January 27, 1900: Measles, 824 cases and 32 deaths; diphtheria, 285 cases

and 53 deaths; laryngeal diphtheria (croup), 28 cases and 8 deaths; scarlet fever, 228 cases and 16 deaths; smallpox, 3 cases; chicken-pox, 41 cases; tuberculosis, 223 cases and 156 deaths; typhoid fever, 28 cases and 7 deaths; cerebrospinal meningitis, 5 deaths.

New Mt. Sinai Hospital.—Prospects for the speedy erection of the new Mt. Sinai Hospital, which is to cover the entire block bounded by Fifth and Madison avenue, One Hundredth and One Hundred and First streets, were discussed at the annual meeting of the directors held on January 28th. The reports of the Treasurer and Finance Committee showed the following assets: Plot of ground for new hospital (cost $531,682.04 less a mortgage of $80,000) $451,682.04; invested in bonds and mortgages, $150.000; cash in hands of Treasurer, $4851.52; building fund (held in trust), $439,174.88. An additional $500,000 must be raised to cover the cost of the new buildings. During the past year 304 patients were turned away because of lack of room.

Insanity among Criminals.—New York State Superintendent of Prisons Collins, in his annual report, which was submitted to the Legislature on January 29th, sets forth that there are now confined at the Matteawan Hospital for Insane Criminals nearly 200 more than the building was designed to accommodate. It was built for 550 patients, while 719 are now crowded into it. This over-population requires the earliest practicable completion of the new hospital at Dannemora, so as to afford the necessary relief at Matteawan. A peculiar fact is that the Elmira Reformatory sent during the last year five times as many insane to the prison as all of the state prisons put together.

The State Sanitarium.—In the report which is to be presented to the Legislature at Albany in support of a bill for a state sanitarium for the treatment of incipient phthisis, the following rules are tabulated and given as embodying the essentials for decreasing the death-rate from consumption or stamping out the disease altogether: (1) The ultimate inclusion, when public opinion is ripe for that step, of consumption in the list of notifiable diseases. (2) Public and official announcement of the fact that, in the event of a person having died of consumption, the rooms occupied by him will be disinfected by the sanitary authorities free of charge. (3) The passing of an act making it illegal to let any house or room in which any person, within two months, has suffered from consumption, without having had it properly disinfected. (4) To make it an offense punishable by fine or imprisonment for any person letting a house or room wilfully to conceal or deny that there has been consumption in the house. (5) To call the attention of shipping agents to the fact that there is danger to a healthy person in occupying the same cabin with a consumptive. (6) To make it compulsory for a consumptive person taking a long voyage by sea to notify the nature of his complaint before starting. (7) To call the attention of railroad companies, or lines connected with well-known health resorts for consumptives, to the necessity for having the sleeping-cars carefully cleaned with some disinfecting solution, and, above all, thoroughly aired. (8) The removal of hospitals for consumptives in large cities to some convenient and open suburb. (9) The exercise of greater care in the inspection of carcases intended for food, and the compulsory rejection of those indicating tubercular disease. (10) The rejection, as an article of fluid food, of the milk of tuberculous cows. (11) The inspection of herds by paid officials, with the view of destroying tuberculous disease, and isolating or destroying tuberculous animals. (12) The prevention of overcrowding among animals intended for consumption as food. (13) The prevention of overcrowding among people. (14) Back to back houses should be condemned, and the height of houses in cities should be in proportion to the width of the streets. (15) Blind alleys should be opened out, and the custom of building houses at right angles to the length of the streets should be forbidden. (16) Dusty occupations should be strictly regulated, so as to minimize the danger to those who are compelled to follow them. (17) Convents and other religious communities should be periodically inspected by some independent authority.

PHILADELPHIA.

Health Report.—Deaths in the city for the week ending January 27th, were 498, a decrease from last week of 27 and a decrease of 20 from the corresponding week of last year. Contagious diseases: Diphtheria, 128 cases, 23 deaths; scarlet fever, 66 cases, 5 deaths; enteric fever, 44 cases, 9 deaths.

German Hospital.—The report of the medical board for 1899 has been submitted. During the year 3631 new patients were admitted and the dispensary visits numbered 45,477. The total number of operations was 1099. A fire-escape with especially wide stairs has been constructed and helpless patients can now be removed with comparative ease and safety.

Circulating Library Closed.—The health officer of Scranton has closed the circulating department of the public library in that place. It was believed that the circulation of books had some part in the spread of diphtheria and scarlet fever which have been epidemic in the town for some time, and which recently caused the closure of certain of its schools. The report of last week shows diphtheria to be decreasing, while scarlet fever is still spreading.

Gift to the University.—Mr. James Dundas Lippincott has made a donation which provides for a private operating-room for the hospital of the University of Pennsylvania in memory of his uncle, James Dundas. The suite will consist of four sections. These include a large operating-

room in the center, a sterilizing-room and a professor's bath-room opening from this on one side, and an etherizing and recovery-room for patients on the other. The erection of this memorial, which will be begun shortly, will give the University one of the finest and best equipped private operating-rooms in any hospital of this country.

Illegal Sale of Drugs.—The Pennsylvania State Board of Pharmacy has just completed a week's session in this city. Three hundred and twelve persons applied to the board for license, one of the successful candidates being a woman. Investigations warrant the belief that evidence sufficient to prosecute has been obtained in 150 cases of illegal drug selling in Philadelphia alone. It is found that opium or morphine and many of the more virulent drugs may be obtained with facility. While looking after these cases the Board also hopes to lessen the adulteration of drugs and the practise of substitution in the preparation of prescriptions.

Antivivisectionists.—The seventeenth annual meeting of the American Antivivisection Society was held in this city January 25th. In an address the corresponding secretary stated that vivisection of human beings was the legitimate outcome of the vivisection of animals. If the torture and dissection of dumb beasts was allowed to continue it would soon become a menace to human beings, not only to the patients of charity hospitals, but also to the citizens outside of institutions. The desire for discovering something new becomes in the investigator a mania which is not satisfied with the lower animals, but impels him to use human subjects as more valuable in the way of obtaining reliable results. There is no doubt that numbers of atrocious and inhuman experiments have been and are being made upon poor patients in the hospitals of European cities and in at least one of our own States, that State being Massachusetts. Dr. Matthew Woods, who was re-elected President, stated that this work was carried on mainly by students instead of physicians. The Gallinger bill was discussed and the systematic introduction of antivivisection ideas into every large city urged.

Typhoid Fever.—The meeting of the Pathological Society, on January 25th, was arranged as a "Symposium upon Typhoid Fever." Dr. A. C. Abbott spoke of the "Epidemiology." Reference was made to the fact that all teaching classed typhoid fever as peculiarly an autumnal disease. The average for many years shows this to be true, but special years show many deviations. The teaching, then, is incorrect for conspicuous typhoid centers. This statement is proven by reference to Philadelphia, which, as a typhoid center, is almost without competition. The sewer overflow in 1898 caused an epidemic in a certain district. This subsided and after a time a second occurred in the same district. This was thought to be due to some of the sewage being caught in the bend of the river near the pumping station, or to the old infection of the reservoir. That typhoid fever is especially an autumnal disease cannot be said where surface water is used.

Dr. J. H. Musser spoke of "The Value of Clinical Laboratory Methods in the Diagnosis of Typhoid Fever." The Widal test is the most important and has proved correct in more than 98 per cent. of his cases. He believes that if proper care in diluting the blood, etc., be exercised it is hardly possible to have a case of typhoid fever in which it will not be positive. This test is not only of value in the diagnosis of typhoid fever, but in determining the nature of processes following that disease, as infection of the biliary passages, the bladder, etc. As to the fact that it is rarely obtained before the fifth day of typhoid being against its practical value, it was stated that it is also seldom that the practitioner sees cases before the fifth day.

Dr. Simon Flexner spoke on the subject of "Typhoid Septicemia." Cases are met with which are easy to diagnosticate clinically, but which are very difficult of diagnosis at the autopsy. From these cases we must believe in the existence of typhoid fever without internal lesions. The demonstration of this depends (1) on the presence of a positive Widal reaction during the life of the patient, and (2) on obtaining the organism from the internal organs at the autopsy. To have a typhoid septicemia it is necessary for the organism to enter the blood and lymph currents. It so does in ordinary cases of the disease, but is soon filtered out by the various organs and hence it is not customary to find it in the blood except in transit. There is a class of cases, however, in which there are no lesions, or only atypical ones, and the bacillus is found throughout the body. These are cases of typhoid septicemia, or, as they should be called, typhoid bacteremias. Considerable observation has shown that this occurs. A number of such cases were found at Manila where, from the slightness of the lesions or their entire absence, the diagnosis upon the autopsy-table would have been extremely difficult. In all these cases the organisms were collected from the blood.

CHICAGO.

Dr. J. G. Huizinga has accepted the professorship of ophthalmology at the Post-Graduate Medical School.

Will of Dr. Hoadley.—The will of the late Dr. Albert E. Hoadley was filed for probate a day or two ago. The testator left an estate valued at $50,000. Of this $40,000 is personal property.

The Doctor's Magazine.—In a few days the first number of this publication will appear under the editorship of Dr. George F. Butler, formerly editor of the *Medical Standard*.

Chicago Surgical Society.—This Society was recently organized, with the following charter members: Drs. John E. Owens, J. B. Murphy, Arthur Dean Bevan, Weller Van Hook, M. L. Harris, A. H. Ferguson, L. L. McArthur, D. A.

K. Steele, W. H. Allport, E. W. Andrews, Carl Beck, S. C. Plummer, Jacob Frank and Daniel N. Eisendrath.

Ocular Therapeutics for the General Practitioner.—At a meeting of the Chicago Medical Society, held January 24th, Dr. Albert B. Hale read a paper on this subject. New drugs from the chemists' laboratory are constantly being added to the physician's table, and some deserve to be retained both by specialists and general practitioners. Among drugs useful in ophthalmic therapeutics we have of the newer ones four that are particularly valuable.

Holocain.—This is a synthetic product, related to phenacetine, so that its name is merely imitative of cocaine, which in many cases it may supplant. Its salt, the hydrochloride, is soluble to about two and a half per cent. in cold water, and should be applied in a one-per-cent. aqueous solution. It has particular advantages for the general practitioner. In removing foreign bodies from the conjunctiva or cornea, for instance, it is better than cocaine, as it acts quicker, causes little pain, does not dilate the pupil, in temporary use effects corneal epithelium less, produces no ischemia, to be followed by hyperemia. It is somewhat antiseptic (enough to keep itself, at least), and can be sterilized by boiling with no disturbance of chemical composition. It must not be injected hypodermatically, nor be applied to other than ocular mucous membrane, as it is systemically poisonous. It must be prepared and kept in porcelain, not glass, as the alkali of the glass influences it.

Euphthalmin.—Of the three effects of local applications to the eye (omitting cautery or astringency), anesthesia, mydriasis, cycloplegia, many drugs produce all three, in varying proportions. Modern chemistry has supplied holocain for simple anesthesia. As yet, no drug produces simple cycloplegia alone. Mydriasis alone, however, can now be produced by euphthalmin, a complex synthetic product. It is best used in a five to ten-per-cent. watery solution. Here the author gives tables and cites authors to prove that cycloplegia is practically absent, and that it can be used in all cases at any age to produce a dilation of pupils for study of lens and fundus. Conclusions: (1) No subjective symptoms produced. (2) Only mydriasis caused, of short duration, beginning in thirty minutes (3) Effects show earlier in youth than age. (4) Ocular tension not increased. (5) No hyperemia or ischemia of conjunctiva produced, corneal epithelium unaffected. (6) Accommodation practically unaffected . (7) Normal pupil soon restored. (8) Non-poisonous apparently.

Protargol.— This is better than any inorganic silver salt yet used. It is a proteid compound, containing about 8 per cent. of silver. Bactericidal power as great as silver nitrate; penetrates deeper; much less painful not so dangerous to epithelium; can be used much more frequently; not so affected by light; its brown color an advantage for local application. Perhaps the silver nitrate is better for direct action on gonococcus, but for all other inflammations or irritations of ocular mucous membranes, protargol in a five- to ten-per-cent. watery solution is much better for the general practitioner.

Extract of Suprarenal Capsule.—Abel (Johns Hopkins) quoted with reference to epinephrin. Bates' experiments confirmed, showing that it is astringent more than hemostatic, acting through uninjured vessel wall. Useful for cosmetic purposes to blanch a red eye, to assist in prolonging anesthesia with cocaine or holocain, to aid other drugs in treating inflammations of conjunctiva. It is an unstable powder, spoils easily in the presence of water, must, therefore, be mixed fresh for use, as it has no well-defined solubility.

GENERAL.

Bubonic Plague.—Dr. Walter Wyman, Surgeon-General Marine Hospital Service, has just published from the Treasury Department a pamphlet on the plague, which will prove of general interest.

The Metric System.—It is hoped by scientists that the bill to secure the adoption of the metric system by the United States which has been introduced in Congress will pass. The bill provides for the use of this system after January 1, 1901, in all departments of the government except in the completion of the survey of public lands, and that after January 1, 1902, the metric system shall be the legal standard of the United States.

Sanatoria in the Riviera.—The British residents at Cannes have established there a sanatorium where officers invalided from the Transvaal will be received as free guests. Six villas have been hired and numbers of rooms taken at the hotels, and private residents have agreed to receive one or more invalids in each of their families, so that accommodations are now ready for four hundred wounded or sick officers at Cannes alone.

The Price of Carbolic Acid.—Owing to a report circulating in New York last week that the British Government had forbidden the export of carbolic acid, the price of that article was doubled. The reason assigned for this was that all the carbolic acid on hand, and all that could be manufactured for some time to come, would be needed for the manufacture of lyddite. Lyddite shells are used extensively in the war with the Boers.

Scruple is supposed by some, says the *Chemist and Druggist*, to be the diminutive of *scrupus*, a sharp stone, from which its meaning as "a scruple of conscience" would also be indicated; but it is more generally traced to *scripulum*, something written, which was exactly the meaning of the Greek small weight *gramma* (from which the French *gramme* was adopted), although it is not

quite easy to see the connection between "something written" and a small weight.

The Influenza.—The "grippe" continues to rage not only in London, but also at various points on the continent. At Berlin during the first half of January the deaths from influenza numbered one hundred and seventeen. At Rome several thousand cases are reported, and at Rouen, in France, the troops garrisoned there and the general population are suffering severely; the public schools are closed. Such an epidemic in Europe as is now raging preceded the first invasion of this country. In all probability we may expect a similar experience now.

Famine in India.—Official estimates made at Calcutta place the number of persons now affected by the famine in British territory at 22,000,000, and in the native states 27,000,000. Lord Curzon, the Viceroy, says the famine area has expanded, surpassing the worst fears, and they are now facing a cattle, water, and food scarcity of a terrible character. Over 3,000,000 persons are now receiving relief. The Viceroy points out that India now will be obliged to struggle alone, as the thoughts of every Englishman in the world are centered on South Africa.

A City of Filth.—A correspondent of the *New York Tribune* writes from Peking, recent date, as follows: "The three chief characteristics of the Chinese capital which most impress the newly arrived visitor are dust, stench, and dogs. There has been no rain since June, and the hideous tracks that are dignified by the title of streets are ankle-deep in black dust, much of which is pulverized filth. Along the macadamized streets, of which there are three, are open drains. These serve as sewers from which the sewage is dipped and the highway sprinkled. When it dries the pulverizing is resumed, and, in addition to the original compound, the residuum of the tainted water is breathed into the lungs."

Death of Dr. Hall.—Dr. George D. Hall of Galveston, Texas, died at his home December 22, 1899. He was born at Newbern, N. C., March 25, 1824, graduated at the University of Pennsylvania in 1848; married in 1854, and was engaged in the practise of medicine at Gaston, Ala., till he entered the Confederate service as assistant surgeon in 1863. At the close of the war he moved to Courtney, Texas, where he was actively engaged in the practise of his profession till a few months before his death. He spent a long and useful life, honored, beloved and lamented by all his acquaintances. He left a widow and son, Dr. George P. Hall, professor of ophthalmology at the Texas State University. Dr. Hall was for fifty-one years, except for a time during the Civil War, a subscriber and reader of the MEDICAL NEWS.

Antivivisection.—Dr. W W. Keen, the president of the American Medical Association, desires it to be announced that some changes have been made in the Senate Committee on the District of Columbia. As members of the profession are requested to send personal letters to these Senators, a revised list of the committee is herewith given: Senator James McMillan, Michigan, Chairman; Senators J. H. Gallinger, New Hampshire; H. C. Hansborough, North Dakota; R. Redfield Proctor, Vermont; J. C. Pritchard, North Carolina; Lucien Baker, Kansas; Thomas S. Martin, Virginia; William M. Stewart, Nevada; Richard Kenney, Delaware; George L. Wellington, Maryland; S. R. Mallory, Florida; W. V. Sullivan, Mississippi, and W. A. Clark, Montana. Personal letters may be addressed to them or to other Senators. Petitions should be addressed to the Senate of the United States.

Sir William MacCormac, London's eminent surgeon, now at the front, writes in the *Lancet*, January 20th, that on the day of the Tugela battle 800 patients passed through the hospitals, all the wounded being cleared off the field within four hours of the end of the battle and despatched to the base within two days. This was largely due to the clean-cut wounds of the Mauser bullet, which are entirely free from contusion and laceration. Out of 309 wounds only eight were caused by shell-fire. The remainder were due to Mauser bullets This great disproportion bears out the dictum that the effect of shell-fire is mainly moral. The mortality among the wounded is less than five per cent. The period of convalescence is so short that seriously wounded men return to duty in from three to five weeks. The system of camp sanitation has practically barred out typhoid and dysentery. These are among the achievements to date of the medical service at the front.

Reduced Fares to Paris Congress.—The Secretary-General of the Congress gives notice of the following reduction in rates:

(1) All the railway companies of France will grant to the members of the Congress a reduction of 50 per cent. upon round trip tickets, as follows: Every member of the Congress will receive, upon application to the Secretary-General, Dr. A. Chauffard, 21, rue de l'Ecole de Médecine, Paris, a ticket which must be stamped at the railroad station where he enters France, upon paying the full price of a single trip to Paris. At Paris the member will have this ticket viséd in the office of the Congress, and it will then serve as a return ticket without additional expense. The journey to Paris having been paid entirely, and the return trip being free, there is, of course, a 50 per cent. reduction. It goes without saying that in order to secure this, the return trip must be to the same point at which the original fare was paid. (2) The French line (La Compagnie Générale Transatlantique) will allow members of the Congress a reduction of 10 per cent. on tickets from New York. (3) The Secretary-General has arranged to provide to early applicants a number of lodgings, including light and service, at the rate of five francs per day; and various agencies also advertise reduced rates for lodgings.

For further particulars and application blanks for membership, address,

Dr. H. B. Jacobs,
Sec'y, American National Committee,
3 W. Franklin street, Baltimore, Md.

The Plague.—The latest news from Honolulu announces thirty-eight deaths from the plague. One victim was a white woman of good class. By order of the Board of Health of Honolulu ten city blocks have been destroyed by fire, this constitutes about one-half of Chinatown and 3,400 Japanese are in quarantine at that port. They are emigrants brought out from Yokohama as contract laborers. The total statistics from Manila, January 22nd, show fourteen cases and eleven deaths. The *British Medical Journal*, January 20th, announces that during the last week in December at Oporto six cases of plague and two deaths occurred, and during the first week of 1900 three cases and one death. No cases are known at any other point in Portugal or Spain. In India the condition grows steadily worse. At Bombay during December the average mortality from the plague was 954 per week, nearly double the death-rate during December, 1898. Famine and its attendant diseases swell the death-rate in the Bombay Presidency. The mortality from general diseases, apart from plague, causes extreme anxiety. From New Caledonia, a French possession east of Australia, come alarming reports regarding the prevalence of plague there since early in December. There were sixteen deaths during the first ten days of the outbreak, and between December 25th and January 9th, eighteen cases occurred and ten deaths. Death from plague is reported to have occurred in the hospital at Adelaide, Australia. It has been suggested that the United States Department of Agriculture be authorized by Congress to establish serum stations at once on islands in the Pacific for the development of Pasteur antitoxin, in order that the government may be prepared to meet any invasion of the bubonic plague. It requires one year to bring the antitoxin to a state of perfection. Plague is reported epidemic in Rosario, Argentine Republic.

Medical Practise in the Philippines.—In a letter from Manila dated December 12, 1899, which appeared in the *Journal of the American Medical Association* last week, Surgeon Major Potter makes some interesting observations "There is no field here for American physicians, for several reasons. In the first place the fees are too small. I was called once to an American house where I had been attending the family, and found a native physician there, sent for in emergency by the servants. He withdrew as soon as I arrived, but I asked him what fee he expected. His reply was that the usual honorarium was *dos pesos*, equal to $1 in our money. He is a *mestizo* of good professional standing and education, a graduate of the University of Barcelona, Spain, in medicine, and yet he only expected $1, gold, for an emergency call to an American family. Among his own people he would probably expect an average of 50 cents, Mexican, equal to 25 cents in gold, for each visit. In the next place, the people who pay for their medical service are well-to-do *mestizos*, and they prefer their own race, who speak both Spanish and Tagalog and use remedies with which the people are familiar. There are plenty of such men here, who have been educated first at the local medical college, which is connected with the University of Manila, and have taken a supplementary degree in Spain. There are also several first-class English physicians here, who attend their own nationality as well as other foreigners, and have a considerable clientele among the wealthy natives. Several American physicians have tried to settle here during the last year; some after leaving the Army or Red Cross organization, others having come out specially for that purpose. With one or two exceptions they have failed to establish a practise and have gone home. Several of them told me that they could not do anything except to "fake it" among our soldiers, on venereal disease, and preferred to quit rather than do so."

Medical War-News.—It certainly speaks volumes for individual competency of the regular army surgeons, as well as for the initiative and emergency powers of adjustment and resource of the numerous civilian surgeons so hastily enrolled, that the one department of the present campaign which stands practically above criticism is the medical. The intelligence department seems to be in a state of abeyance or suspended animation, and the chief thing that the private soldier, in his home letters, hopes for from "Lord Bobs" is a better food-supply, but the corps of our professional brethren gets little but praise. Bloody battle-fields are absolutely cleared of wounded before sunset; men seriously wounded are returning to duty in two or three weeks' time; the mortality among the wounded has been kept down to 5 per cent., and dysentery and typhoid, although present in almost every town-camp occupied, have been kept successfully at bay. Yet the medical corps was notoriously undermanned, the latest reports now showing the roster to have been 500 names short of the proper quota. Study leave was proportionately hard to obtain, the social standing of the officers was anything but satisfactory, and some of the best men were leaving it in disgust.

"The luck of the British army," in Kipling's phrase, has stood by it, however, and the blast of war has suddenly galvanized this small but gallant body of men into almost superhuman activity, retired surgeon-majors and colonels even have volunteered by scores for active service again, and the War Office has been simply flooded by offers of civilian surgeons for service. With a liberality as wise as it is belated, the Government, having secured the services of patriotic leaders of modern surgery, Treves, Watson Cheyne, Stokes, MacCormac, has assigned them an adequate rank, salary and staff. And this

somewhat incongruous triple combination is not merely "muddling through somehow," as Lord "Charlie" Beresford predicts of the army, but scoring a success. Of course there is plenty of small friction and jealousy, especially on the part of the army medical men who consider themselves superseded by these great "consulting" appointments, but, so strong is the devotion to duty and recognition of the gravity of the emergency in all ranks of the profession involved, that all are pulling together in harmony upon the main issues.

The report of the chairman of the English Red Cross organization makes, next to the records of the medical arm of the service, the pleasantest reading of the war news. The fitting up of the Princess of Wales' hospital-ship, of the Princess Christian's especial ambulance train, of the Sievewright convalescent homes, the distribution of newspapers and magazines among the troops, and the supply of fresh vegetables and fruits to the wounded in the various hospitals are all achievements of which the society may well be proud. The "Maine" and four field hospitals, the Duke of Portland, the Van Alen, the Langman, and the Lord Iveagh are also working under the society and affiliated with it.

In consequence of a suggestion recently made in the newspapers that trained cooks should be sent out with the hospitals and hospital ships, as well as trained nurses and surgeons, much interest is being taken in the results of the American experiments in training soldiers in invalid-cookery now being carried out in Washington Barracks. The idea is very favorably received in London, and it is not unlikely that our example will be shortly followed in some of the English regiments.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, January 20, 1900.

CASTLES AND COUNTRY HOUSES FOR THE WOUNDED—UNAPPRECIATED PHILANTHROPY—VIOLATION OF THE CODE OF CIVILIZED WAR—INFLUENCE OF MATERNAL INEBRIETY—ECHOES OF PAGET—PATRIOTISM IN THE PROFESSION.

The patriotic movement for the care of the soldiers invalided home from South Africa has now spread beyond the hospitals and sanatoria and reached private homes and mansions. The Duke of Norfolk and Lady Mary Howard have thrown open Arundel castle for this noble purpose and a score of country residences have been placed at the disposal of the War Office, among them those of Lady Wolsley (wife of the Commander-in-Chief), Lady Loder, Mrs. Hope, and the Countess of Carrington. At this rate of progress, if it be not actually "sweet to die for one's country" it will not be so desperately bitter to be wounded for it.

It scarcely appears, however, as if so very much of this nobly generous hospitality would be actually made use of, as the recovery-rate at the collecting and base hospitals is so high and rapid, that only a small percentage of the wounded and invalided have to be brought home at all. Upon these the effect of the long sea-voyage and the good nursing and feeding is so marked that upon arrival here a large percentage of them are almost well again, or at least declare themselves so, and anxious to return to the front. For instance, our old friend of the Cunard line, the "Aurania," arrived this week with 146 invalids from the Modder River, but of these only six were unable to walk or hobble on shore, although they had nearly all been carried on board at Cape Town.

The display of the universal brotherhood of humanity and things remedial and medical by the fitting out in England of an ambulance and corps for the Boer wounded seems to have been far from a success. Sir James Silverwright, an ex-cabinet minister of Cape Colony, who equipped the entire outfit at his own expense, offered at the same time his residence and estate, some thirty miles from Cape Town, as the site of a hospital colony for the English wounded. But instead of appreciating this impartial liberality, both belligerents resented it, and the ambulance was first declined by President Kruger, and then the estate by the Imperial authorities. Later, however, the estate was accepted for hospital purposes by the Red Cross Society, and the surgeons of the commission, although minus their ambulance, have been received at Pretoria and permitted to attend the wounded collected there, both Boer and captured British, making, we hear, no distinction between them, so that some good may come of Sir James' offers after all. The secret of the trouble appears to have been a report, probably quite unfounded, that the donor had let slip an expression to the effect that possibly the Boers might win, and hence was believed to be trying to "keep solid" with both sides at once.

Another violation of the code of civilized war is now being alleged on the part of the Boers. In addition to firing on the Geneva Cross, either upon ambulances or upon the uniform of the bearer corps, they are accused of throwing their dead into the rivers by night to conceal their losses. The effects upon the water-supply scarcely appear to have really occurred to their untutored minds, although there are not wanting allegations of sinister purpose in this regard, especially in view of the fact that the English camps are for the most part down-stream from the Boers.

In a paper based upon the study of 100 cases of female drunkenness read before the quarterly meeting of the Society for the Study of Inebriety this week, Dr. William C. Sullivan comes to the following conclusions: (1) That maternal

inebriety produces a high rate of infant mortality. (2) That with the increase of maternal drunkenness came decrease of infant vitality. (3) That nervous abnormalities were unusually frequent in the surviving children. The first of these conclusions is almost axiomatic and its truth an unmixed blessing to the race as tending to eliminate rapidly and comparatively painlessly this type of organism. As to the other two, there is great difficulty in distinguishing accurately between cause and effect. How far inebriety itself is to be regarded as a symptom or evidence of inherited nervous unbalance is an open and much disputed question. Hence the nervous abnormalities in the children of inebriates may be simply manifestations in the second generation of the same strain of nerve-degeneracy which showed as inebriety in the preceding one, and not in any true sense caused by the alcohol consumed by the parents.

The columns of the press, both lay and medical, are still full of praise and regretful reminiscences of Sir James Paget. The hold which he had upon the admiration of all classes and the large niche which he filled in public esteem were simply phenomenal. His patient industry, his fund of knowledge, his splendid eloquence and his ready wit in speech and repartee are celebrated on all hands. A patient supplies an excellent illustration of his readiness in philosophic epigram. Standing one day at the bedside of one whose successful treatment depended in large measure upon the checking of long-continued alcoholic excesses, the poor wreck of a man begged piteously for some mitigation of his sentence to total abstinence, "You'll let me keep on with a few glasses of whisky and soda, doctor? It's so hard to break off old habits all at once." To which the paradoxical reply came instantly, "All habits are bad—even good ones." A dictum in point of philosophic insight and point worthy of Montaigne. Upon another occasion he is reported to have horrified his prohibitionist friends by declaring in the course of a discussion that "The worst subject for a critical surgical operation is a hard drinker—the next worst a total abstainer." Anent which it must be remembered that the total abstainer is the exception in England and is still, rather whimsically to transatlantic eyes, regarded as a man whose constitution or self-control will not permit him to stand the strain of even moderate indulgence in alcohol. We have actually heard a certain form of eye-strain characterized by a well-known ophthalmologist as "milk-drinker's asthenopia."

The degree to which the whole structure of English society is stirred by the present war crisis is well illustrated in the attitude of our own profession. Not merely have scores of our brethren volunteered their services to the various regiments in their professional capacity, but a strong movement toward volunteering as combatants is now on foot. Our distinguished half-brother in medicine, Dr. A. Conan Doyle, has already offered himself for enlistment in the Imperial Yeomanry, but being rejected as overweight, has taken service upon one of the ambulance-staffs. This week's medical journals published a formal appeal to medical students and the younger members of the profession, signed by Dr. Frederic Roberts, Mr. Edmund Owen and three prominent surgeons, representatives of the Militia, the Volunteers and the Yeomanry. This urges them to consider the duty incumbent upon them to respond to their country's needs by at least filling the gaps in the strength of these forces, made by the drafts upon them for active service at the front. This extraordinary appeal is only one of a hundred indications of the seriousness with which the situation is here regarded.

Not a few members of our profession have already gone to South Africa at their own expense on the chance of getting accepted for surgical service in some of the emergencies which are sure to arise in the field or at the hospitals during the war. Indeed, as already reported, the disappearance of the post-graduate student from the schools and hospitals continues to be one of the striking features of medical London.

TRANSACTIONS OF FOREIGN SOCIETIES.

INTESTINAL INTOXICATION ARISING FROM FOOD-SUPPURATIVE PAROTIDITIS — SUTURE OF HEPATIC CYSTS WITHOUT DRAINAGE—MISLEADING RADIOGRAPHS OF OLD FRACTURES—INTESTINAL OBSTRUCTION BY A HUGE GALL-STONE—THE RECENT EPIDEMIC OF TYPHOID FEVER.

At the Medical Society of the Hospitals, December 22d, Rendu described a case of intestinal intoxication which had recently come to his notice, in which the origin of the trouble seemed to be food, although the symptoms in some respects resembled those of typhoid fever, and in other respects those of malaria. A boy aged nineteen years, living in miserable surroundings and eating mostly spoiled food, was taken ill with headache, pain in the back, anorexia, coated tongue, fetid breath, vomiting, etc., but there was no diarrhea, nor iliac gurgling. There was, however, a sore throat and a scarlatinoform eruption limited to the distal portions of the extremities. This eruption disappeared in a couple of days and was not followed by desquamation. Usually in cases of food-poisoning there is a sudden rise of temperature to 104°, which lasts two or three days and then diminishes rapidly. In this patient the fever was of an intermittent type. In a period of fifteen days he had five or six febrile attacks, each preceded by a chill, and separated by intervals in which there was no fever. Rendu supposed at the time that possibly an old malaria had been stirred up by the gastro-intestinal trouble, but the patient denied ever having had malaria. Admitting that the fever was due to the food, it was

still impossible to make out the exact nature of the poison. In support of the theory that the new attacks of fever were due to intestinal poison, it was stated that the contents of the intestine remained putrid for two weeks in spite of the repeated administration of purgatives and intestinal antiseptics.

Barth said that in his opinion the alimentary intoxication was the *primum movens* of the trouble, but that the succeeding febrile attacks were caused by infection, the influence of the poisonous food-products having exalted the virulence of microbes existing in the intestine.

Claisse recently had opportunity to observe two patients suffering from suppurative parotiditis, the bacillary agent being, as is usually the case, the yellow staphylococcus. It is well established that the infection proceeds from the mouth upward, the first lesion being a stomatitis, followed quickly by an intense gingivitis. Thence the infection travels along Steno's duct. Such inflammation of the buccal cavity is due to a diminution of salivary secretion on account of a special diet ordered the patient or from other cause. Under such conditions antisepsis of the mouth is impossible, and Claisse adopted the plan of increasing the secretion of saliva by injections of artificial serum. Under this treatment the buccal lesions were soon cured. Under circumstances in which suppurative parotiditis is to be feared, namely, in the presence of urinary difficulties, during recovery from severe typhoid fever, pneumonia, etc., the condition of the posterior molars should be carefully looked after, as deposits of tartar can irritate the orifice of Steno's duct. If, in spite of cleansing of the mouth, the gums remain inflamed and the mouth is dry, injections of artificial serum should be resorted to.

Menetrier treated a case of double suppurative parotiditis by expression of the pus along the duct, and the patient recovered without incision. The bacterial agent was the pneumococcus.

Widal mentioned a case of parotiditis after typhoid fever which recovered without incision, the bacterial agent being Eberth's bacillus.

At the Society of Surgery December 27th, Delbet discussed the treatment of echinococcus cysts of the liver, basing his remarks upon a report of four cases made by Jonnesco, who closes the cavity either with or without suture of its walls, but in every instance without drainage. The idea was previously held that the cavity left by the extraction of the cyst membrane must be filled with some fluid in order to prevent exudation of serum. Experience has shown that exudation does not take place. If the cysts are very small no treatment except excision is required. If large they may be closed by a superficial row of sutures, or, if the walls are not disposed to fall together, they may be sutured in layers. In no case should drainage be used. He agrees with Jonnesco that irrigation with strong antiseptic solutions is harmful, while that with weaker solutions is unnecessary. A simple wiping of the cavity with dry gauze is enough. Puncture of a cyst to be followed by injection of parasitic fluids, ought to be given up altogether. Jonnesco's four patients recovered promptly. Counting also four patients operated upon by Bobroff, four by Garre, one by Nelaton, one by Bougle and seven by himself, Delbet made up a total of twenty-one operations performed in the manner indicated without any injection.

Tuffier said that he had operated successfully upon a retrovesical cyst and one of the kidney, using no drainage and not suturing in layers. The patients recovered promptly and were well seven and eighteen months afterward.

Lucas Championniere spoke of the dangers of being misled by a radiograph of a callus after fracture, if the light was held in a wrong position when the radiograph was made. Even when manual examination shows the bone to be united in a good position a radiograph may make it look much deformed. In consequence some surgeons have denied the accuracy of these shadow pictures. There is danger also that they may be used to influence the mind of a jury in a suit for malpractise. The volume, dimensions and form of the shadow vary not only with the distance of the object from the plate, but from the light as well, so that two successive radiographs, unless the bone, the photographic plate, and the light are in exactly the same positions, will show two different deformities at the site of fracture. This variation in the size of objects is readily shown by taking a radiograph of a hand holding a needle and then taking a second one with the light at a greater distance. The needle in the former case may easily appear twice as long in comparison to the bones of the hand as it does in the latter. These facts should be borne in mind in forming an opinion from a radiograph as to the amount of deformity which follows a fracture.

Tuffier showed a smooth intestinal calculus about the size of an egg which had caused symptoms of intestinal obstruction, and which he had removed by laparotomy. The patient, curiously enough, had never suffered from bilious colic, although it seemed probable that the stone was formed in the gall-bladder and had passed thence into the intestine in the same condition as when found, as there were no signs of new stratification.

At the Society of Pediatrics Netter communicated some statistics relative to the recent epidemic of typhoid fever in Paris. He treated 188 patients of whom 6.65 per cent died. Hemorrhage was observed six times, erythema three times. The severe cases were characterized by cardiac complications by a small pulse and a tendency to collapse, and often by bronchitis and cerebrospinal symptoms. In these severe cases warm baths were employed, as with children they are better borne and give better results than cold baths. Among his patients were two nursing infants, both of whom died.

Marfan said that he had many times examined the blood of nursing infants with fever, but had failed to obtain a serum-reaction with typhoid

bacilli. It is probable that typhoid in an infant may pass unnoticed. Even in older children the reaction appears late, if at all.

Mery was able to obtain a positive serum-reaction in the case of an infant eight months old. The mortality among 67 patients treated by him during the epidemic was 7.45 per cent. In severe cases he used cold baths and did not consider them ill-borne by children. The indications for the use of the cold bath in children are the same as for its use in adults.

Ausset said that he had examined the intestines of many children who had died from various diseases; but that he had never found the lesions of typhoid fever when the disease had not been recognized during life.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The Ninety-fourth Annual Meeting Held at Albany, January 30 and 31, and February 1, 1900.

FIRST DAY—JANUARY 30.

MORNING SESSION.

Inaugural Address.—Dr. Willis G. Macdonald of Albany formally opened the first session of the ninety-fourth annual meeting. He said:

"The general interests of the Society have not alone sustained but materially advanced during the year. The interests of higher medical education have been safeguarded. The number of scientific contributions voluntarily presented to the program show no lack of healthy professional spirit. There have been presented few evidences of professional discord. Larger problems in sanitation in the State care of infectious diseases are now confronting us and the people will undoubtedly act upon our conclusions.

Sects in Medicine.—The recent development of several sects in medicine, the underlying principles of which have no bases in fact, presents a serious menace to public health which from the peculiarity of the methods employed by these sects, makes it very difficult and, under the present law, absolutely impossible to control. To state it more briefly, the doctor of Christian science and of osteopathy and the trance medium can all avoid the consequences of the medical practitioner's act. This condition arises from the insufficiency of the legal definition of the term "practise of medicine." A number of gentlemen of large experience, both medical and legal, have undertaken to so define the term "practise of medicine" that all these species of quackery may be controlled by our present medical practise act. To this end I commend the hearty support of this Society or its co-operation with the New York Academy of Medicine.

Medical Expert Witnesses.—There are a few propositions concerning this matter which present themselves to my mind: The medical expert witness is neither better nor worse than any other expert witness, and the difference of opinion among electrical, mechanical, chemical and even legal experts are just as great as among medical. The essence of the whole thing is bias. When a medical expert prepares for an attorney the medical side of a case and prompts him in the examination of opposing witnesses, he is no longer a witness and should not be sworn. He is an advocate at the bar with all the bias that that implies. The legal profession is responsible for the present order of things. When they start out to obtain expert medical testimony they frequently and very naturally look for the witness who is going to be of the most assistance to them, both as a witness and in the preparation of their side of the case. Presiding judges can readily remedy this by excluding from the witness box the medical advocates. I am of the opinion that a voluntary society of men doing expert work could do much to regulate the condition.

State Control of Tuberculosis.—The question of State control or care of persons suffering from chronic infectious diseases is receiving world-wide attention. The regulation of tenement houses, and of food supplies are important topics for consideration. The United Charity Organizations of New York, if I am correctly informed, have come to the conclusion that State care is the solution of the tuberculosis problem. There are other ways of approaching the proposition of the control of tuberculosis than through the organization of State sanatoria. The State devoted, by appropriation, to the State care of the insane during the year 1899 over five million dollars. What additional appropriations may very naturally be required for the support of the tubercular, the syphilitic, the venereal, and, eventually, the cancerous? Such a series of conditions would soon evolve a condition of philanthropic communism. We must be guarded in our advocacy of these measures. The suggestion is made that the seal of approval of this Society shall not be placed on suggested legislation until the most careful consideration.

Affiliations.—The events leading to the schism now existing between the American Medical Association and the Medical Society of the State of New York are too well understood to require any repetition in this body, nor would any reference to it be made but for the unofficial discussion by individual members of each society of a plan for reapproachment. The principles for which each faction in the New York State Medical Society has striven so strenuously and honestly for twenty years have under the influence of medical progress become practically identical. There lingers yet but the memories of thrusts received in heated if not acrimonious debate, and of wrongs perpetrated in defense of false notions. Personally, after a critical investigation I can find no difference in the ethical behavior of members of the American Medical

Association and that of members of the Medical Society of the State of New York. In fact, some very worthy and distinguished physicians are members of both and reflect equal credit upon each society. It has occurred to many of us that honesty and good manners are not matters for legislation or codes, but rather the results of home training and education, and that physicians are well bred and honest because of education rather than codes. The present medical law of the State of New York has done more to remove sects in medicine and improve the ethical and scientific standing of physicians than all the codes since Hyppocrates. It is this law, possibly somewhat modified, with some additional safeguards, that is the code of ethics of the Medical Society of the State of New York, and practically unifies the profession in this State. If the present requirements for the degree of doctor of medicine in New York State will not guarantee the ethical behavior of the candidate, no code will. His State certificate is his authority and you can decline to receive, resolve and expel until red in the face, yet sit with the same man on an official board of health the next day.

The cases are isolated indeed where the code of the American Medical Association has been invoked to discipline a member. Its most frequent use has been its employment to keep members of this Society from participating in the meetings of the American Medical Association. Recently this policy of conciliation has led to the acceptance of members of the Medical Society of the State of New York as members of the American Medical Association without asking any questions or having the gentleman recommended by another. The practise seems to me not only questionable but undignified. The differences which led to the disruption have disappeared. There is nothing but the echoes of strife and a few personal ambitions. A solution of the problem might be simple. Let the American Medical Association invite the Medical Society of the State of New York to send delegates whose credentials will be received and they be admitted through the same door that closed in the faces of that distinguished delegation of New York physicians at St. Louis. Let them come in the front door of the convention with equal rights with all, in this way, I believe, can our differences be settled with dignity, and the Association made what it is not now, the representative of the united medical profession of the United States.

Vivisection in the District of Columbia.—There are two subects of great importance to the medical profession now subjects of legislation before Congress. The first is a bill purporting to regulate vivisection in the District of Columbia, but which is in reality a measure designed to annoy, hamper and nullify every effort made for the advancement of medical science through humane animal experimentation. It is only in the rarest instances that cruelty has been inflicted. It is certainly not necessary to detain this Society by any detailed statement of the manifold benefits which so continuously flow from animal inoculation and experimentation in the field of original research.

Medical Corps of the Army.—The other subject is of equal interest to us and involves the reorganization and increase of the medical corps of the army. Skeleton formation is a favorable plan in other departments of the army, why does it not apply in the medical corps? There can be no doubt that the Surgeon-General has been very modest in his demands for increase in the personnel of the medical corps. If army medicine and surgery are going to be held responsible for all the ills of the camp and field, it should have at least an adequate corps. Our duty is plain, we should at once go to the assistance of the medical corps and make Congress feel the necessity of prompt and favorable action.

Executive Business.—Dr. A. Vander Veer, of Albany introduced a resolution that this Society request our Senators and our Representatives in Congress to give hearty endorsement to the law, now pending, regulating the increase of the medical corps of the army; it was carried.

A question as to the eligibility to membership to the State Society of the West End Medical Association of New York excited much discussion. A subcommittee reported favorably upon the eligibility of a delegate from that Association without any endorsement from the Society as a whole.

Gastric Carcinoma and Hydrochloric Acid.—Dr. A. MacFarlane of Albany read this paper. He said that symptoms of carcinoma of the pylorus are very different from those involving other parts of the stomach, the signs of a diffuse growth differing from those of a localized tumor, the evidence of an ulcerating tumor differs from that of one which has not ulcerated, the symptoms of a primary growth differing from those where the tumor has subsequently developed. The significance, then, of the presence or absence of retention, hydrochloric acid, lactic acid, blood, pus, sarcinæ, yeast, should not be applied indiscriminately to all cancerous conditions, but to selected cases in which the agent is present.

He wished to call attention to a series of sixteen cases in which what is ordinarily considered the most characteristic symptom of carcinoma—absence of hydrochloric acid—was not present. Some claim that absence of hydrochloric acid is pathognomic of cancer; it certainly is of the highest diagnostic significance. Hollman, Biach, Eisenlohr, Tapret, Piqual, Koch and Bruvert have reported cases showing that the presence of hydrochloric acid is not necessarily inconsistent with the diagnosis of cancer. Of these sixteen cases reported, in twelve of which the diagnosis was confirmed by operation or post-mortem examination, six had histories highly suggestive of a preceding ulcer. Hydrochloric acid was continuously present in thirteen, and for a time found in the other three, where it was later replaced by lactic acid. The pylorus was involved in seven

cases, the pylorus and lesser curvature alone in one, and the growth was diffuse in one case. Lactic acid was present late in four patients, in three replacing the hydrochloric acid and in one associated with it. All suffered greatly from vomiting retention, determined by the presence of sarcinæ or food, was well marked, emaciations and loss of strength were striking in every case and the appetite was poor in most cases. The duration of the gastric symptoms in nine cases was less than a year, in seven more than a number of years. In seven cases the pain was the prominent symptom, while distress and burning were mentioned in three. Of the sixteen cases, eleven occurred in the male and five in the female, the ages varying from thirty to seventy-two years.

The object of the paper was not to add to the difficulties of diagnosis, but to impress the importance of the possibility in a considerable number of cases of the absence of the most characteristic symptom of carcinoma and the necessity of judging each case by itself.

Age, Sex and Season in Nervous Disorders.—Dr. William C. Krauss of Buffalo showed the importance of age in the history of development of nervous disease. He divided the period of life into six epochs, showing those diseases which have a predilection for each epoch The period of adolescence is one of active growth and gives rise to certain functional disorders, such as chorea. During the epoch of manhood there is impairment of bodily functions and degenerations, which result in organic diseases.

Strabismus.—Dr. D. B. St. John Roosa of New York read this paper. At the last meeting of the Society he reported a new operation for this condition. Confidence in that operation was based on the fact that Panas operated 210 times before he reported on the subject. He now reports results of 6 operations, since increased to 24, and by his colleagues, Dr. Davis and the house surgeon at the Manhattan Eye and Ear Hospital, to 48. Of these only two cases still require operation. The operation consists essentially in stretching both muscles to be divided before dividing them. The other feature of the operation consists in doing it at one sitting. The case should not be an ambulatory one if success is to be attained.

Non-operative Treatment of Strabismus.—Dr. A. E. Davis of New York read a paper on this subject, as follows:

(1) Hypermetropia and hypermetropic astigmatism are the causes of convergent strabismus in the great majority of cases.

(2) As contributory causes may be mentioned, (a) difference in acuteness of vision, either congenital or acquired, but usually acquired and due to an unequal state of refraction in the two eyes; (b) anything that interferes with the acuteness of vision, as opacities on the cornea, in the vitreous or lens.

(3) Faulty structure, insertion or innervation of the extrinsic muscles of the eye may cause convergent strabismus; and paresis of the ciliary muscles has been given by some observers (Javal).

(4) The amblyopia present in most cases of convergent strabismus is functional and acquired, and not congenital except in rare cases. The few examples of positive evidence on this point, that is, where cases have improved greatly in vision when the squinting eye was straightened, together with the cases where the amblyopia has been observed to develop after the strabismus begins, as in the case furnished by Roosa, and published for the first time in this paper, are of much more value than all of the negative evidence in favor of the theory of congenital amblyopia.

(5) The non-operative treatment of strabismus, tropine, the exclusion pad, and in patients old enough, glasses, the stereoscope and bar-reading, should be begun as soon as the squinting is observed; for it is in the early cases that this form of treatment is capable of doing so much good. By means of it, if the case is taken in time, false fixation and suppression of the image in the squinting eye is prevented, fusion of the images in the two eyes encouraged, and form-perception, that is, true binocular single vision often maintained. Even where one or more of these functions have been lost persistent effort in the non-operative methods of treatment frequently restores them.

(6) Just as soon as the non-operative method of treatment ceases to improve the condition of the squint it is time to operate. Delay in operating after this is not only useless but harmful, because the habit of suppressing the image in the squinting eye becomes fixed and the amblyopia worse.

(7) After the eyes have been operated on, the use of the stereoscope, bar-reading, the pad, glasses and so forth, are of the utmost use in completing the cure, maintaining parallelism and establishing single binocular vision.

(8) The "rational" treatment of strabismus is early treatment, and in every case the child should be thoroughly examined soon after the strabismus begins. This principle should be urged upon the whole profession in order that it may reach the public.

Ocular Affections in Family Practise.—Dr. Frank Van Fleet of New York read this paper. To his mind there are four kinds of conjunctivitis: Simple, which requires very little treatment; gonorrheal; trachomatous, and traumatic. All forms are purulent and contagious, excepting possibly the traumatic form The treatment depends on the severity and the cause producing it. Mild attacks require only a soothing collyrium; severe attacks require an application of nitrate of silver, and, possibly, ice-cloths. The use of a mild solution of nitrate of silver, five grains to the ounce, in mild attacks, is best. It is applied with a cotton-wrapped applicator. To gonorrheal cases the stronger solutions, from twenty to forty grains to the ounce are advisable; if applied early enough they may not need repeating; application of ice-cloths should follow. Trachoma and follicular conjunctivitis, when acute, respond

promptly to the application of nitrate of silver. After the acute stage, apply sulphate of copper. Any one of the three remedies, nitrate of silver, alum, or sulphate of copper, will produce good results in the treatment of conjunctival inflammations if used for a limited time; if used too long they may aggravate the trouble. In acute cases, use the silver; in the subacute and chronic cases, use all three alternately. Conjunctivitis may be mistaken for other conditions, the most common being keratitis, iritis, scleritis and glaucoma. In conjunctivitis the striking characteristic is the discharge of pus, more or less profuse. In keratitis there is an increased flow of the lachrymal secretion. In conjunctivitis there is swelling and redness; not so in keratitis. In keratitis there is loss in the brilliancy of the cornea; not so in an uncomplicated case of conjunctivitis. In the majority of cases of keratitis there will be an opacity of the cornea. In conjunctivitis there will be an injection of the conjunctival vessels; in keratitis there will be few or none, although what is known as circumcorneal injection, which is never found in uncomplicated conjunctivitis, may be observed.

Iritis and glaucoma should be differentiated from keratitis. In keratitis there is generally an abrasion or ulceration of the cornea. In keratitis the pupil is contracted; in glaucoma it is dilated. In keratitis the cornea is sensitive to the touch; not so in glaucoma. The irritation due to keratitis will entirely disappear for a time under the use of cocaine; in iritis it has little or no effect. If cocaine dilates the pupil in iritis it will cause an irregular outline. Pain is generally more pronounced in iritis and glaucoma than in keratitis. In glaucoma there is increased tension of the eye.

The pain of conjunctivitis is relieved, as a rule, by the application of iced compresses; in keratitis and iritis hot applications are preferred. In uncomplicated conjunctivitis atropine is never indicated; in keratitis and iritis, always; while in glaucoma it produces the most disastrous results. Episcleritis and scleritis are often met with in private practise as frequent accompaniments of rheumatism and gout. The treatment consists in the application of hot water and atropine. Internally large doses of salicylate of soda, free catharsis, and alkaline waters. Colchicum is often of value.

Under-Graduate and Post-Graduate Instruction in Therapeutics.—Dr. Eli H. Long of Buffalo read a very practical paper on the teaching of therapeutics to under-graduates and with reference to post-graduate instruction. Dr. Reynold W. Wilcox of New York thought that less attention should be paid to theoretical and more to the practical side of instruction.

AFTERNOON SESSION—TUESDAY.

Earache in Children.—Dr. T. H. Halsted of Syracuse read this paper. It will appear in the MEDICAL NEWS.

Weil's Disease.—Dr. Harlow Brooks of New York read this paper. Weil thinks this disease to be an infectious toxemia. It is almost always found in consumers of putrid or spoiled animal flesh, and is quite frequently seen in butchers. The lesion of the disease results in swelling, congestion with blood extravasation, parenchymatous nephritis, and degeneration of the liver. A great similarity exists between fatal cases of Weil's disease and acute yellow atrophy of the liver. Weil's disease, yellow fever, acute yellow atrophy of the liver and results of phosphorus poisoning present similar pathological changes.

Fever and Heart Failure.—Dr. A. Jacobi of New York read a paper on the treatment of temperature and heart failure. He does not believe that any degree of temperature or any Greek name of a disease should be treated in place of the patient.

Croupous Pneumonia: Pathogenesis and Treatment.—Dr. James K. Crook of New York said that we know that the cocci are present in the majority of the cases of this disease, and, further, that if we inject a pure culture into animals, it gives rise to hepatization of the lungs. They are not invariably present in pneumonia, nor do they invariably cause pneumonia, nor do they fulfil all the laws that the pathogenic organisms do, as in the case of the bacillus anthrax, Koch's bacillus, or the spirillum of relapsing fever. Pye-Smith, in an article in Albutt's "System of Medicine," requires that the microbes should be specific, and the cultures identified beyond dispute. The morphology of the diplococcus of Fräenkel is admitted to be illusory; it is arbitrarily described as a micrococcus, a diplococcus, or a streptococcus. It is also described as being oval, or lancet-shaped, or as a bacillus; as sometimes encapsulated, and sometimes not. It must be confessed that we can not pin our faith in Fräenkel's microbe as a cause of acute lobar pneumonia, nor as a basis for therapeutic measures. Two French writers have shown the presence of the pneumococcus in the secretions from the tonsils in every one of forty persons. While it is possible to reach the lungs through the blood-vessels or the lymphatics, it may be shown that the bacillus also gains an entrance through the bronchial tubes. There is no doubt that a depressed vitality increases the receptivity of the soil. Dr. Andrew H. Smith[1] claims that pneumonia is not an inflammation by a process of germ culture. That opinion is at variance with those of other writers on the subject.

It has been discovered that the serum from the blood of animals affected with pneumonia gives temporary immunity when injected into healthy animals. The hope is that the future treatment rests in the discovery of a practical antitoxin. Many believe that an antitoxin can be introduced into the stomach of a patient and so into the body in such a way as to render the blood an unfit medium for the pneumococcus. We should not be in too great a hurry to attempt to jugulate a disease by the use of antiseptics until the re-

[1] MEDICAL NEWS, December 16, 1899.

sults of the antiseptics are better known, and whether they can be introduced in sufficient strength to destroy the pneumococcus without destroying the patient.

Dr. Andrew H. Smith of New York, in discussion, referred to the double circulation existing in the lungs, one being in common with the circulation of all other organs in the body which sustains the structural conditions; the other circulation being functional. It is possible to have a disease which affects one circulation and not the other. If the liver is compressed by an exudate the functional circulation is absolutely suppressed; yet in the lung the structural integrity is maintained and it may later expand. In no other organ in the body is such a thing possible. In pneumonia and diphtheria the specific germ acts locally and gives rise to an antitoxin, which is absorbed into the system and disseminated everywhere throughout the body, producing serious symptoms. They are equally interesting in regard to other dissimilarity; in diphtheria the microbe works in the tissues; in pneumonia the microbe acts upon the exudate, which is essentially outside the body and not a part of the structure of the lungs. The microbe and toxin are directed upon the tissue just as truly as if they were corrosive poisons.

Classification of Infectious Diseases.—Dr. William H. Thomson of New York believes in the adoption of a definite nomenclature descriptive of classes of infectious diseases, as follows:

(1) All diseases due to the presence of specific living micro-organisms are infectious; therefore, owing to the nature, all infectious diseases are inoculable from the sick to the well; according to the means of communication he classified them under three headings, *viz.*: (*a*) Contagious; (*b*) non-contagious; (*c*) inoculable. The contagious communicable diseases are transfered by simple proximity; this is sufficient to communicate the infection to those who are susceptible; among these diseases are typhus fever, typhoid fever, smallpox, measles, mumps, whooping-cough, etc. The practical deduction is that these should be isolated to prevent infection.

(2) Non-contagious communicable diseases are those in which the communication is not by simple proximity to the sick, but by other intermediate means. Isolation is not needed nor is it effective. Examples are Asiatic cholera, tuberculosis, etc.

(3) Inoculable diseases are those in which the infection gains an entrance through a wound or damage to the skin or mucous membrane, such as surgical infection of wounds, hydrophobia, tetanus, and in addition, malarial infection as proven experimentally from the bite of the mosquito.

Prophylaxis in Gynecology.—Various papers were presented in this discussion, for which see pages 164 to 167 in this issue of the MEDICAL NEWS.

Dr. M. D. Mann of Buffalo referred to the imperfect development and hygiene of school-girls, especially at the time of puberty. There is too much pushing of young minds deveolped at the expense of the body. Young girls, at time of menstruation, should be removed from schools and kept quiet. In older people such care need not be given at the menstrual period. Regarding abortion there are three kinds of infection: (1) Infection from saprophites or a sapremia, usually recoverable. (2) Staphylococcic and streptococcic infection, usually of severe nature and often fatal. (3) Gonococcic infection, which comes on, not from neglect, but because it existed previously in the cervical canal and makes its way up to the tubes and ovaries

EVENING SESSION—TUESDAY.

Discussion—State Care of Tuberculosis Patients.

Dr. Edward O. Otis of Boston, Mass., opened the discussion. One-seventh of all deaths are the result of tuberculosis. It is the most prevalent of all diseases. It is curable in the early stages. The helpless cases among the poor have no care and so must go to almshouses. The situation should arouse the public to action. He advises that the crusade against consumption be made a popular one. He favors two kinds of public institutions, *viz.*: (1) Consumptive hospitals in or near the cities, regulated by municipal control. (2) Several state sanatoria favorably situated for the climatic and open-air treatment and not too far distant from the city. The cost is not much over $400 *per capita* per year. Efforts at treatment among the poor in their homes are almost impossible. He referred to the progress made abroad in establishing sanatoria, and trusted that this country would soon do likewise and not be so apathetic.

State Care in Massachusetts.—Dr. Vincent Y. Bowdich of Boston, Mass., read this paper. The number of cases in the hospital previous to October 1, 1899, 212; readmitted, 2; total, 214. The number discharged, 126; still under treatment, 88. In 35 the disease was arrested; 37 were much improved; 17 moderately improved; 24 not improved; 1 had bronchitis and 1 died, the latter having tuberculosis of the bladder. The point of great interest pertains to the arrested cases. He uses the term *arrested* and not *cured*, because he does not consider it should be applied until the patients have been under observation two years.

Infectious Character of Tubercuolosis.—Dr. George Blumer of Albany continued the discussion. In tuberculosis developing in later life, evidence shows that the bacillus may enter in several ways, of which the two most important are the respiratory and alimentary tracts, rarely the genito-urinary tract or through the skin. The alimentary tract is affected more commonly in children than in adults. The rarity of primary intestinal tuberculosis is shown in 1000 autopsies reported with only 1 case. Northrup of New York in 125 necropsies found but 3 with uncom-

plicated tuberculosis of the mesentery glands. Infection through the genito-urinary tract is extremely rare, and then is probably of blood origin. The prognosis studied from a pathological standpoint shows that no chronic disease shows a greater tendency to heal.

Legislation Concerning Tuberculosis.—The Hon. Horace White of Syracuse said that two years ago a committee was appointed to introduce a bill showing the wisdom of making an appropriation for the establishment of a hospital for the victims of pulmonary consumption. Last winter a bill was introduced for the establishment of such a hospital. It failed. This winter again was presented another measure of the same character. He believes that the future will bring the desired results. What has been accomplished elsewhere can be accomplished here. The only adverse argument advanced seems to be the expense to the State. He believes the relief is sure to come.

Spread of Tuberculosis.—Dr. Enoch V. Stoddard of Rochester discussed the sanitary and economic standpoints. One of the commonest causes of poverty is the prevalence of disease by which families are deprived of the helping hand. It is not well known, but the State of New York, in both private and benevolent institutions, aids one in 251 of population. The cure of tuberculosis in home sanatoria is less frequent than when patients are in distant localities and distant climates. He advised the enforcement of a policy by the Legislature regarding the prevention of tuberculosis, which should be as adequate as that which controls smallpox or other contagion.

Increased Taxation Necessary.—Hon. Otto Kelsey of Geneseo said the State is not prepared to assume this tremendous burden. It costs about $550 *per capita* to build buildings for housing the dependent classes. The charges of State Government are about $23,000,000, causing a tax of 2½ mills on the dollar, which, added to the municipal and local tax, makes a burden. Of this amount $5,000,000 is for the insane; $4,000,000 for schools; $2,000,000 for the canals; $11,500,000 for prisons and other necessary appropriations. The sum of $300,000 is now being used for new buildings for the insane. The practical question to be submitted in face of the enormous expenditure is: Is it proper or safe to venture upon another great expenditure so indefinite that the extent to which it may go cannot be estimated.

Dr. John H. Pryor of Buffalo stated that tuberculosis caused 12,079 deaths last year against 13,414 this year, and increased nearly 500 this year. In Greater New York there were over 300 more deaths this year than last. He believes in isolation-hospitals near large cities, and that there should be State prevention. We can be compared with Turkey in Europe and compared with no other country in Europe. Even Spain is establishing hospitals for consumptives. The Empire State cannot afford to be surpassed in this by European countries and her sister States.

WEDNESDAY, JANUARY 31ST.

MORNING SESSION.

The first part of the morning was devoted to a Clinical Session given at the new Albany Hospital. Special trolley cars were run to within a few blocks of the hospital; the doctors were then transferred to 'bus and sleigh, and carried to the hospital door. The clinic was under the control of Dr. Vander Veer. The courtesies of the hospital had been extended to members of the Society desiring to bring patients, and such patients were cared for, free of charge, during their sojourn in Albany.

Drs. Vander Veer and MacDonald showed many interesting cases, chiefly surgical, and Dr. W. K. Otis of New York read a paper on "The Modern Urethroscope; Its Value and Limitations," showing his latest invention in this field. At the termination of the clinic the members of the Society were carried back to the City Hall, where the regular program was resumed.

Anthrax.—Dr. Frank W. Ross of Elmira, in reading this paper, said: The lesions are typical and can hardly be mistaken for anything else. The wonderful results of immunizing serum used in animals should justify its use in man. Excisions of the infected part and the application of the antiseptic, both locally and by injection, justify their prompt and persistent use in all cases.

Bovin's Tuberculosis.—James Law, M.D., of Ithaca said that some of the medical profession and the lay skeptics denied the possibility of the transference of the disease from ox to man and from man to ox. Cultures of tubercular bacilli from man to the rabbit and cultivated then in bouillon become more destructive to guinea-pigs. In the tuberculin test for tuberculosis in herds, the majority of animals show only a localized tuberculosis. There are countries where tuberculosis is prevalent in man and not in animals. There is an increase of bovine tuberculosis in New York State because cattle are admitted without examination; Canada, Massachusetts, New Jersey, Pennsylvania, Illinois and Kansas will not admit the milch cow without tuberculin test being used.

Tuberculin Tests.—Dr. V A. Moore of Ithaca stated that the tuberculin of to-day is a concentrated liquid usually in glycerinated bouillon, in which the tubercle bacillus grows until it can grow no longer. The practical application is very important; the tuberculin reaction consists in the temporary rise of temperature on the part of the tuberculous animal; it produces absolutely no effect upon healthy animals.

Dr. James K. Crook of New York referred to cases occurring in hospital, where it was important to know if those were true cases of tuberculosis. In three tuberculosis was diagnosticated clinically and in three it was suspected. In none was there any reaction from the injection of tuberculin except one which turned out to be tuberculosis. Three doses of tuberculin were administered, beginning with 1 milligram.

The Medical Examiner.—Dr. S. Oakley Vanderpoel of New York read this paper. All life insurance companies formerly were obliged to decline from 12 to 15 per cent. of applicants on account of impairment of family record or physical disability. Recently one company studied all its declined applications between the years 1875 and 1890 and learned the condition of health if alive and the cause of death if dead. From the data received the company was able to differentiate and collect groups of cases suffering from the same disorders; now, practically all of the 15 per cent. formerly declined are accepted on a substandard basis, provided they are not actually ill or there is no moral hazard. His conclusions were: (1) The company now insures underaverage, as well as selected lives; it offers insurance to practically all who apply. (2) In each case it adjusts the plan of insurance to the insurance value of the risk. (3) The medical examiner's report serves as a basis of valuation, and determines the plan upon which the insurance is offered.

The Angiotribe.—Dr. J. Riddle Goffe of New York related his experience with this instrument, and reported sixteen cases in which he had used it successfully. The advantages are: (1) It secures absolutely against hemorrhage. (2) It shortens the operation of vaginal hysterectomy ten to fifteen minutes. (3) It seals the severed ends of the broad ligaments, thus preventing absorption of septic material. (4) As the work proceeds more and more room is gained for manipulation in the pelvis. (5) It is easily applied in cases in which the uterus cannot be drawn down.

Dr. Stone of Washington said the use of the instrument enables one to remove the uterus and close up the vaginal wound entirely without fear of hemorrhage or of suppuration. The two points of advantage referred to were: (1) It shortens the operation, and (2) avoids the use of silk ligature in the pelvis or abdomen.

Acute Otitis Media.—Dr. Edward B. Dench of New York said that severe pain in the ear is due to inflammation of the external auditory canal or tympanic cavity. If one looks in the ear of a child and finds nothing, the teeth should then be examined for carious conditions. Earache in children usually means inflammation of the middle ear; in adults it may mean inflammation of the external auditory canal or tympanic cavity. A high temperature, unaccounted for, almost invariably is due to inflammatory conditions within the tympanum. An absence of luster of the drum membrane means an inflammation just as redness does. If the drum membrane is to be incised, make a free incision. Cut and cut deeply every time. Do not use drops, in the ear, of sweet oil and laudanum; this should be a state's-prison offense. Dry heat, hot-water bags or some other form of dry heat should be employed. Never use poulticing or syringing of the ear, except in the presence of pus.

Dr. James F. McKernon of New York believed in the instillation of an eleven per cent. solution of camphor at the temperature of the body, in pain in the ear.

Uterine Fibroids.—Dr. W. F. Ford of Utica read this paper. It will appear later in the Medical News.

The Anniversary Address was delivered by the President. (See page 193 of this issue.)

WEDNESDAY—AFTERNOON SESSION.

The following subjects were discussed at the opening of the session: Dr. Samuel G. Grant of New York demonstrated several instruments for use in rectal examinations and operations. "A Unique Case in Obstetrics," was read by Dr. F. H. Parker of Auburn. "Further Investigations into the Cause of Cancer," was read by Dr. Roswell Park of Buffalo. The two latter papers will appear later in our columns.

Curability of Leprosy.—Dr. George Henry Fox of New York said it was possible for leprosy to be cured. It is a disease like syphilis tending to run a slow and definite course; when the virulence is spent, the patient is free from the disease, if the strength is sufficient to stand a prolonged attack. Emphasis was laid upon the hopeful condition of the mind. Chalmoogra oil is of great benefit in all cases. In a case of macular leprosy he had been able to administer 100 drops of this oil; when the stomach rebelled, nux vomica was given and the patient greatly improved. The oil is of benefit in the tubercular form as well. Change of climate is a potent factor in the treatment.

The Care of the Hair.—Dr. George Thomas Jackson of New York read this paper, which will appear later in our columns.

Dr. Robert C. Myles of New York read a paper entitled "Some Remarks on the Surgery of the Nasal Septum," and presented some anatomical specimens, showing certain deformities, and described the methods used for the correction of the same.

Dr. Orlando B. Douglass of New York said that the value of the surgical treatment of nasal obstruction, which causes more than nine-tenths of all the catarrhal troubles, can hardly be overestimated.

Dr. John O. Roe of Rochester referred to the fact that nasal obstruction is the most potent cause of nasal catarrh, and operation should be instituted for its cure.

Hip-joint Disease.—Dr. A. M. Phelps of New York showed a boy with hip disease to whom he had applied the so-called "lateral traction-fixation" splint. The brace should extend above and below the joint. In hospital the use of the brace is followed by less than 16 per cent. of abscesses. Different varieties of braces were demonstrated.

Education and the Medical Profession.—A. V. V. Raymond, D.D., LL.D., President of Union University, delivered this address. Education stands for liberal culture; the profession of medicine stands for technical knowledge, skill and a means of livelihood. Is the aim of education to

give man ability for his special calling? No. Man's occupation is not the end but the means to the end. The principle involved is that true education comprehends the development of all capacities and powers belonging to man, bringing him into correspondence with all the world. He is educated because he is a man. A longer period of preparatory training is needed for medical students than any other profession; it required the best men and the best methods.

Rational Therapeutics vs. Christian Science.—James M. Bulkley, D.D., LL.D., of New York, editor of the *Christian Advocate*, delivered this address. With more knowledge it is said freaks could be accounted for. Health is a condition of ease in existence, sickness is a disease, local, general, functional or organic. The causes of disease, scientifically considered, are accident, overwork, internal poison, germs, and the operation of destructive forces from without. Old age is recognized as normal. Superstition is the attempt to account for natural effects by supernatural causes, or diseased or modified natural results by supernatural means. Whenever a point is made against a lecturer or advocate of Christian Science this person holds he is not responsible for any view offered. What they do hold is a simple paraphrase of Mrs. Eddy's sayings. Much laughter was created by reading some of Mrs. Eddy's theories. He then proceeded to demolish them, *seriatim*.

Surgery of the Stomach.—Dr. H. Beeckman Delatour of Brooklyn reported one case of gastrotomy and one case of gastrectomy. The latter operation took fifty-five minutes. Hunger was a marked feature. The patient rapidly increased in weight, gaining thirty or forty pounds six months after operation. The patient became pregnant and gave birth to a child. The patient is still alive, although there was a recurrence coincident with pregnancy.

Atresia of the Vagina.—Dr. F. W. Higgins of Cortland said that diphtheria is one of the rarer causes of this condition, only two cases having been previously reported. He had operated successfully on a case due to this cause. Twenty-four ounces of blood were found in the dilated uterus and vagina. Operation should be performed early, before the Fallapion tubes become dilated; strict asepsis is necessary. Flushing the cavity with hot saline solution, wiping dry and packing with iodoform gauze was advised.

Governor Roosevelt, at 5 o'clock, tendered to the members, delegates, invited guests and their friends, a reception at the Executive Mansion. In the evening the annual dinner was served, at the Hotel Ten Eyck.

THURSDAY—FEBRUARY 1.

MORNING SESSION.

Dr. Luzerne Covelle of Ithaca discussed in a paper the shape of the spleen and its surgical relations. This was followed by a paper by Dr. William Mabon of Ogdensburg, on "Surgical Operations in Hospitals for the Insane," in which he discussed the advisability of such work. Operative procedures on insane inmates are being practised quite extensively and reports of beneficial results are not uncommon. The general health is thereby improved and indirectly this improves the mental condition.

Hysteromyomectomy.—Dr. I. S. Stone of Washington, present by invitation, favored supravaginal hysteromyomectomy in the great majority of cases in preference to myomectomy simply. The latter operation is attended with greater mortality and always leaves the patient with the possibility of developing more tumors. Twelve cases were reported.

Cerebrospinal Fluid.—Dr. W. Freidenthal of New York reported a case of cerebrospinal fluid discharged through the nose. There is no connection in these cases with nasal hydrorrhea or hay-fever, which are purely nervous in origin. There is a constant dripping from the nose day and night. This is usually preceded by severe brain symptoms, which are relieved by the discharge. Dr. Scheppegrell of New Orleans, in discussing this paper, insisted that the symptoms favored the supposition that there is a tumor near the hypophysis cerebri and through presence of this tumor fluid is discharged. There is no mucus in the discharge.

Inguinal Hernia.—Dr. Thomas P. Scully of Rome presented the comparative results of radical operative treatment and treatment by injections, with report of cases.

At the executive session Dr. Ransom, in behalf of the Committee on Medical Expert Testimony, reported that there is no prospect of obtaining corrective legislation in view of the constitutional restrictions, and upon request the Committee was discharged.

Election of Officers.—The following officers were elected: President, George B. Fowler of New York; vice-president, George Seymour of Utica; secretary, Frederic C. Curtis of Albany; treasurer, O. D. Ball of Albany. The standing committees remain as before, with the exception of the addition of A. G. Root of Albany and A. E. Davis of New York to the Committee of Arrangements; John H. Pryor of Buffalo to the Committee on Hygiene; T. Z. Jones of Waterville to the Committee on Ethics, and O. D. Ball of Albany to the Committee on Publication.

Emulsion of Cod Liver Oil.—The emulsion with glycerin here given contains eighty per cent. of the oil, is very stable, and not unpleasant to the taste.

℞ Ol. morrhuæ pur. ..... ʒ vi
Glycerini pur. ..... ʒ i
Tinct. quillaiæ ..... ʒ iss
Aq. laurocerasi ..... ʒ i.

M. Ft. emuls. Sig. Shake well. Dose as directed. If the addition of hypophosphite of calcium is deemed desirable, one dram of the salt dissolved in five drams of water is added to the above emulsion.

VOL. LXXVI. NEW YORK, SATURDAY, FEBRUARY 10, 1900. NO. 6.

ORIGINAL ARTICLES.

THE POLICY OF THE STATE RELATIVE TO THE SPREAD OF TUBERCULOSIS.[1]

BY ENOCH V. STODDARD, M.D.,
OF ROCHESTER, N. Y.;
VICE-PRESIDENT OF THE STATE BOARD OF CHARITIES.

LONG continued observation and carefully conducted scientific research have established the fact that consumption, or pulmonary tuberculosis, is not only a universally prevalent disease, but that its specific character places it among the contagia. These two facts, being accepted as proven, suggest the importance of the immediate adoption of measures for the abatement of this extended evil. In the consideration of means for the accomplishment of this end we are made aware that it is not society only which demands consideration or which is involved, but that the State, in its broader supervisory function, is even more directly interested than the merely social organization.

It is a universally accepted aphorism that the strength and permanence of any State depends upon the health and vigor of its citizens, and that anything which may lessen these characteristics correspondingly reacts upon the productive capacities and general welfare of the State. We have thus two points of view from which to examine the relation of the State to any form of disease especially one which is liable to become generally prevalent and to exert a baneful influence upon the health of its communities. The first of these we may designate as sanitary; and the second as the economic standpoint.

The sanitary welfare of the community has for a considerable period been a subject of solicitous and careful consideration. The causes tending to produce disease and to favor its extension have been scrutinized with scientific care; and, when recognized, have been subjected to legislative provisions for their control or removal. There has thus grown up in our communities, and under a general State supervision, a department of public health. Under favoring legislation an elaborately organized system of health boards, with extended powers, has been established in nearly every community in this State. The powers granted by legislation to such boards have been extensive and, in some respects, absolute, with the design of ensuring promptness and efficiency in stamping out those forms of disease which are known to be contagious or infectious. It is only recently, however, that tuberculosis has been recognized as belonging to the class of contagious diseases. This fact assured, it at once becomes necessary for the State to take such measures as shall place this disease under the same restrictions and provisions as are established for other diseases of a contagious character.

A second point of view referred to is an economic one. It has been ascertained by sad experience that one of the common causes of poverty and pauperism is the prevalence of disease by which the individual is deprived of his capacity for self-maintenance, or the bread winner of the family is removed from his place as provider for a number. In either case the State becomes the loser in proportion to the productive capacity and character of the individual suffering from disease. This fact opens a question of great importance to that department of society and State supervision whose function it is to search out the causes and to establish measures for the relief of such conditions. This at once brings into co-operation the health authorities of the State and the department of supervision of its charitable administration.

Viewed from this two-fold standpoint the question becomes a vitally important one, and the inquiry naturally arises, what shall be the policy of the State in dealing with it?

It is already well known that the number of deaths annually occurring in the State of New York from tuberculosis amount to nearly fourteen thousand; while the incipient and chronic cases of disease existing each year reach the startling figure of about sixty thousand. With the knowledge which we now possess of the preventability of this disease, as well as of the poverty directly traceable to it, the importance of the adoption of a definite policy, by the State, looking towards the diminution and the ultimate eradication of this disease is all important.

It has been suggested that legislation be enacted by which the State shall assume the care of all cases of tuberculosis occurring among the poorer classes of our communities, and that to secure this end sanatoria or hospitals be established by the State to which such dependent cases can be sent for care and treatment. From a casual or sentimental view, such a course may recommend itself; but careful consideration of the subject, in its broadest phase, leads to the rejection of a proposition for such universal care. It is known and appreciated by comparatively few that the State of New York, under its present system of charitable administration of public and private benevolence is already contributing to a greater or less extent to the maintainance of one in every two hundred and fifty-one of its population. The impracticability of carrying out so

[1] Read in the discussion on "State Care of Tuberculous Patients" at the annual meeting of the Medical Society of the State of New York, held at Albany, January 30, 31, and February 1, 1900.

extended a system, as has been proposed, of providing for the tuberculosis cases by the State becomes apparent. It would seem, therefore, that the province of the State is not so much to assume the direct and detailed care of such patients as to establish such a system, by well advised legislation, as shall enable the several communities of the State to bear their proper part in the care, each of its own dependent cases.

The conclusion that it is not climate, nor sunshine, nor locality, nor life in the open air, nor medical treatment alone which is necessary for the cure of the tuberculous patient, but *the judicious use of each and all of these agencies in the treatment of each individual case*, is being universally accepted. It is not so much the gathering of the incipient and chronic cases into sanatoria and hospitals, and their maintenance there, which we seek to accomplish, as it is to *educate* the patient in the care of himself, and the public at large in these measures which not only provide for the care of the sick, but for the protection of the community, by instructing its members in the means of prevention as well as of cure.

The province of the State, therefore, would be mainly educational, and only custodial so far as might be necessary to ensure these object lessons in care which might be required by some of its communities whose provisions for such education were limited. Those under whose ministrations the sick and needy fall are well aware of the reluctance which they exhibit in regard to removal from their homes. In our larger municipalities, where numbers of the lower and poorer classes are aggregated closely in unsuitable surroundings, the scourge of tuberculosis is found to be mose prevalent. The aversion of people so situated to removal from their homes to any distant institution, no matter how well appointed or how hopeful a provision may be extended to them for a cure, is an almost insuperable barrier to any efforts which would involve their transfer from the neighborhood of their own home. Such circumstances and conditions suggest the importance of establishing a system, by which the sick of any district can be provided for in a local hospital or sanatorium or in the vicinity of their own homes. The importance of what might be called the home sanatorium becomes more and more evident upon farther study. The State of New York possesses, in its extensive variety of hill, valley and upland, sites in the vicinity of almost every center of population, well adapted for the establishment of such sanatoria. The sick poor are more easily led to seek relief in such an institution than in one necessitating an absence from home and friends and a long journey by public conveyance.

It is held by those who have had extended experience in the care of these cases that the cure of tuberculosis in the home sanatorium is less likely to be followed by a relapse than when the cure is accomplished in a distant locality and different climate.

An equally important consideration connected with the home sanatorium is its educational capacity. Such an establishment immediately becomes a center of instruction for the people among whom it is situated. They not only learn the proper care of the consumptive in such hospital and when sick, but are instructed in the best means to be adopted in the home in order to prevent the entrance and spread of the infecting germ of tuberculosis. Each patient in such a sanatorium, after such stay as may be prescribed by the medical attendant, is returned to his home, not only well instructed in maintaining a proper care of himself, but with a knowledge which becomes at once a source of education to his family and neighbors in the proper preventive and curative treatment of the disease.

These conclusions accepted, the policy of the State in the prevention of tuberculosis does not seem difficult of definition. It involves two propositions: First, a legislative one, by means of which may be established a system of control of those conditions favoring the development and spread of this disease; and, second, a provision for the establishment of its educational functions by instituting one or more sanatoria, by means of which the knowledge of the best methods of treatment and prevention can be generally disseminated.

In outlining a policy to be followed by the State, it must be understood at the outset that reference is had to provisions by the State for *incipient* cases only, chronic cases being provided for by the several communities in which they are found. Such provision is already rendered possible by the law, enacted by the last legislature, providing for the establishment by large municipalities, in their immediate vicinity, of hospitals for the care of pulmonary tuberculosis. If this capacity of local provision for chronic cases is extended to incipient cases, an important part of the remaining problem will be solved. The State already possesses a well and carefuly developed system of protecting the public health. Under existing statutes every city, town and village maintains its board of health. Legislation, extending the powers of such health boards by placing tuberculosis among or in the class of contagious diseases, would at once establish an efficient series of local sanatoria under a carefully devised and expert supervision.

It would not be difficult, therefore, to found a system of state hospitals under the general supervision of the State Board of Health, state hospitals proper being under boards of managers, appointed by the Governor and the Senate, while local hospitals would be managed directly by local boards of health, but being still under a general State supervision. The enactment of a law by the Legislature, containing these provisions, would at once develop a series of local hospitals for the care of incipient as well as chronic cases of tuberculosis, in the vicinity of the great centers of population. These would serve as stimuli to the residents of the smaller towns and villages in the establishment of their own hospitals. There could thus be adopted and enforced in every household,

a policy, in regard to tuberculosis, which would exert a power of prevention sufficient to control the existence and development of this disease, as fully as of smallpox or any other of the contagia.

THE JUSTO-MAJOR PELVIS AS A FACTOR IN THE CAUSATION OF PERINEAL INJURIES.

By JOSEPH BROWN COOKE, M.D.,
OF NEW YORK;
LATE ATTENDING PHYSICIAN TO ST. MARY'S FREE HOSPITAL FOR CHILDREN, OUT-DOOR DEPARTMENT, ETC.

It is, of course, a self-evident fact that among patients with justo-major pelves the obstruction offered to the descent of the fetal head is inversely proportionate to the size of the bony ring through which it has to pass, and that lacerations of the maternal soft parts are apt to occur as a result of precipitate labor or of malpositions of the presenting pole. Nevertheless, it is customary with many practitioners to give a favorable prognosis in such cases, and the patient or her husband is assured that the labor is bound to be easy because the pelvis is usually large and roomy. Such a prognosis is seldom verified in the lying-in chamber, as almost any obstetrician's case-book will show.

Posterior positions of the occiput, face, brow and compound presentations, prolapse of the cord and similar abnormalities all fall to the share of the "large and roomy pelvis," and set at naught the encouraging prognosis given weeks before.

Granting, however, a normal position of the vertex (occiput anterior) the outcome is seldom much better, and it is this class of cases to which particular attention is called. In such the first stage is apt to be tedious, the head does not engage readily, flexion is seldom complete and often rotation is improperly accomplished; the second stage is no better than the first, while, to make a bad matter worse, the maternal soft parts are almost invariably badly lacerated when the head passes through the vulva.

Notwithstanding the fact that with an anesthetic and careful management of the head its passage through the vulva can be controlled exactly, it is difficult to prevent this accident. The most rational explanation thereof seems to be that owing to the abnormally increased caliber of the justo-major pelvis the head does not "mold," and when it is delivered it distends the maternal soft parts to an excessive degree. It has, in fact, all the characteristics of a head in a breech delivery. Of course, if the infant is small the perineum may be saved, but women with justo-major pelves do not as a rule bear small children.

The following brief outline of a case will serve to illustrate this type of labor:

M. T., American, twenty-two years of age, primpara, one of twenty-four children. The patient is a woman of fair height, proportionately well built, strong and healthy. Her external pelvic measurements are:

	Cm.	Average.
External Conjugate	21.5	(20¼)
Ant. Sup. Spines	31.	(26)
Post. Sup. Spines	10.	(9⅘)
Iliac Crests	31.	(29)
Intertrochanteric	33.	(31)

The sacral promontory is well out of reach.

Six days before the birth of her child labor pains began and lasted for about twelve hours. Abdominal examination showed the fetus to be lying in the first position (L. O. A.). By vaginal examination the head was found to be almost resting on the pelvic floor, with the os uteri directed backward toward the sacrum and dilated to a diameter of about 3 cm. The membranes were intact; fetal heart 140. When her pains stopped she was allowed to go on from day to day under the care of a competent nurse, who was instructed to report at once the onset of any untoward symptoms. At the end of six days her pains returned and she was delivered naturally in seven hours. During the latter part of the second stage chloroform was given in sufficient quantity to prevent too rapid expulsion of the head, and every effort was made to save the perineum, which in spite of the utmost care was torn nearly to the sphincter. The child weighed seven and one-quarter pounds and its head was nearly globular, showing no signs of any molding or compression whatsoever. The lacerated tissues were repaired at once.

There is apparently no help for these cases, unless it be episiotomy judiciously performed, a procedure which the writer mentions only to condemn. Beyond this the physician can only bend every effort toward saving the soft parts with well-timed anesthesia and proper manipulation. For the rest, he should give a guarded prognosis and stand ready to perform an immediate and complete perineorrhaphy should circumstances require it.

REPORT OF BACTERIOLOGICAL INVESTIGATIONS UPON YELLOW FEVER.[1]

By ARISTIDES AGRAMONTE, M.D.,
ACTING ASSISTANT SURGEON U. S. ARMY.

Preface.—A report upon investigations carried out in Santiago de Cuba in the summer of 1898 was rendered before the work referred to in the present writing was begun. Frequent reference is made to it as "Report, December, 1898."

The bacillus icteroides, claimed by Dr. G. Sanarelli to be the causative agent of yellow fever, received particular attention, and having unexpectedly found it in three instances which certainly were not yellow fever cases, we can the more regret that the amount of work, which was excessive for one single investigator, did not

[1] This report embraces the research work undertaken in the City of Havana by order of the Surgeon General of the United States Army. It was begun early in December, 1898, and suspended in November, 1899; including a period of six weeks spent at Santiago de Cuba during the last epidemic.

allow the planting of material from many other than undisputed cases of yellow fever cadavers.

Hog-cholera, under the name of *pintadilla,* is a disease which prevails in this island to an enormous extent. Its pathogenic organism must be widely disseminated, and I do not doubt that careful cultures from the organs of cases of typhoid, chronic dysentery and the obscure fevers which are endemically met here, would reveal the bacillus icteroides as one of the many secondary invaders in the last septicemic processes.

Introduction.—In the summer of 1897 there appeared before the medical world from the pen of the renowned bacteriologist Giuseppe Sanarelli, a "memoire" upon studies he had made in Montevideo that enabled him to isolate a bacillus which in his opinion was the specific pathogenic organism of yellow fever. The discovery being announced by such a savant and through the columns of the *Annals of the Pasteur Institute of Paris,* it caused profound sensation: the work was published in several languages and in a comparatively short period the scientific world tacitly accepted the claims of Sanarelli and patiently awaited the preparation of the prophylactic serum, which was announced as already undergoing manufacture.

Cultures of Sanarelli's bacillus icteroides were secured in various laboratories and experimental work begun for the purpose of verifying his assertions. Unfortunately, indeed, for science and humanity, the results obtained have been most unsatisfactory; they lack that uniformity which is so essential and constant in all truly scientific facts. Even in the hands of Sanarelli's stanchest supporters this organism has behaved differently from the way described by the discoverer (DeLacerda and Ramos., *Archiv. de Med. Experimentale,* May, 1899); the frequency with which it has been found in the yellow fever cadavers varies with different investigators.

At the time of the epidemic which overran the littoral of Mississippi and Louisiana in the fall of 1897 much research was undertaken with the results herein briefly summarized. Dr. O. L. Pothier in his report of work performed at the Isolation Hospital, New Orleans, La. (*Jour. Am. Med. Assoc.,* April 16, 1898, p. 884-888) claims to have found Sanarelli's bacillus in only three out of fifty-one yellow fever autopsies; yet such result leads him to conclude that this organism is the "special cause of yellow fever." But that is not all, it happens that he did not isolate bacillus icteroides, for the organism which he describes required from 3.5 c.c. to 5 c.c. of a 24-hour bouillon culture to kill a rabbit; and a dog injected with 5 c.c. of a 24-hour bouillon culture, intravenously, survived even after a subsequent injection of 10 c.c., while the bacillus claimed by Sanarelli as his discovery proves fatal to rabbits in doses of 1 c.c. or 1.5 c.c., and to dogs from 3 c.c. to 5 c.c.

Drs. Wasdin and Geddings of the Marine Hospital Service, in a preliminary and separate report of the work performed during the same epidemic (Public Health Reports, Washington, D. C., Nov., 1898, vol. xiii., No. 45), give what at first glance would appear as more satisfactory results. They claim to have found the bacillus icteroides in thirteen out of sixteen cultures made from yellow fever cadavers (the number not stated) and declare that their results "indicate that the bacillus icteroides of Sanarelli is the specific agent in the causation of yellow fever." (Geddings.)

In July of the current year we were presented with a complete and final report from these gentlemen of their original investigations upon the "Cause of Yellow Fever," in which, with evidently genuine candor, it is claimed that "in the blood of yellow fever cases extracted during life bacillus icteroides has been found in thirteen of the fourteen cases, with one negative, a per cent. of 92.85." (Report on Cause of Yellow Fever, p. 25. Also Medical News, Aug. 26, 1899, p. 266.)

To the average reader this statement would not seem at all remarkable if it were not for the fact that the result was reached, not through skillful and painstaking technic, but the reverse. All that Drs. Wasdin and Geddings had to do was to prick the lobe of the ear, collect the blood therefrom in glass bulbs, plant in bouillon and after a short period (not stated) plate from these cultures; and lo! bacillus icteroides occurred in every case but one. The degree of contamination which takes place by such procedure can easily be appreciated by the merest tyro in bacteriology. How Drs. Wasdin and Geddings can place any reliance upon results thus obtained is something that we cannot explain, knowing as we do their extensive scientific attainments.

In the same report we find this statement: "In this negative case Dr. Meacham obtained bacillus icteroides post-mortem." The writer is in a position to correct this mistake having received from Major Meacham a culture of the organism which he believed to be bacillus icteroides and which he had isolated from the case of Manuel Corujo (No. 9 in the Wasdin-Geddings Report) and *not* from Pedro Quintela (No. 14 in the Report) as stated by Wasdin and Geddings. On page 25 of their report, Drs. Wasdin and Geddings say, "In thirteen instances we isolated bacillus icteroides in pure culture." This statement is misleading, to say the least. Once the organism is isolated it must necessarily be in pure culture, or else it will *not* be *isolated.* If the remark quoted is intended to convey the idea that bacillus icteroides *occurred* in pure culture, then the statement is at fault, indeed, for in the same report we read that in Case No. 1, it was associated "with bacillus proteus vulgaris and bacillus coli[2];" in Case No. 5, with "bacillus coli;" in Case No. 7, they obtained at the same time colonies "also of two other organisms, one a colon;" in Case No. 10 it

[2] The bacillus coli (Escherich) Mig. is used throughout this report for the bacterium coli commune of Escherich.—Migula, p. 734.

occurred "together with a variety of bacillus coli;" in Case No. 22, the blood gave "mixed cultures of bacillus icteroides and bacillus coli." When associated with other organisms it could not have been present in pure cultures.

The fifth "conclusion" arrived at by the Commission (Report on the Cause of Yellow Fever) is to the effect that "cases do occur in which the bacillus icteroides cannot be found in the blood or organs in which it might be deposited." Yet, the Commission was so fortunate that in the fourteen cases examined here (Havana) it found the bacillus icteroides in the blood or in the organs where it had been deposited therefrom. Whence was the above quoted conclusion drawn? From the failure of others to find it?

The writer does not propose to make a detailed criticism here of the "Report on the Cause of Yellow Fever," but as his results in spite of apparently more careful methods than those employed by Drs. Wasdin and Geddings have been so very much unlike the achievements of these gentlemen, he thinks it not inopportune to call attention to the assertions and contradictory statements quoted above.

The fact that bacillus icteroides is often agglutinated and its motility arrested by the normal serum of the horse, dog, rabbit and other animals as well as by the serum of many persons who never had yellow fever, which fact has been ascertained by Novy,[1] Wasdin and Geddings,[2] and by the writer, certainly argues very strongly against the specificity of this organism in yellow fever. The fact that it promptly agglutinates by the action of hog-cholera serum in very high dilution again speaks most eloquently against the imputed relation it is said to bear upon the causation of yellow fever; Drs. Reed and Carroll have clearly established a close relationship between bacillus icteroides and bacillus cholera suis.[3] Finally, the incontrovertible fact that no protection to infection by bacillus icteroides is afforded by the serum of real yellow fever convalescents seems to very pointedly indicate that the relations between this organism and the disease in question must be of a most indirect or evanescent character.

In following the course of his bacteriologic investigations, the writer was compelled to abandon the digestive and respiratory tracts, which, upon planting therefrom, invariably produced such luxuriant growths as to very materially obstruct the process of isolation and classification; cultures were made principally from the blood during life, the heart blood, liver, spleen, kidney, bile and urine, the methods employed being described in the text. In the report handed to you in December, 1898, we said: "The work I have the pleasure to record here is far from ended," etc. Allow me to add to-day that the work here recorded is still "far from ended," moreover, that it will never be, until every investigator understands that his duty is not to join the ranks that will promote personal aggrandizement, that he must not undertake research with preconceived conclusions, but that his labor must ever lie in the narrow path of unalloyed scientific truth. The writer must confess that the *cause* of yellow fever has escaped him; but the series of disappointments to which this research has subjected him are certainly amply repaid by the promising results derived from his attempts at serum-therapy.

Conclusions.—1. The specific pathogenic microorganism of yellow fever is as yet an unknown entity in spite of the work reported by various observers; apparently, new methods of cultivation must be initiated or new culture media devised in future research.

2. The bacillus icteroides of Sanarelli, lately (1897) asserted to be the causative agent of yellow fever, is no more concerned in the production of this disease than the common colon bacilli which are constantly found in the blood and viscera of individuals suffering or dead from yellow fever.

3. When approved bacteriological methods are employed, the bacillus of Sanarelli does not, as a rule, appear in cultures from the blood of yellow fever patients.

4. Bacillus icteroides may be and has been found present in the tissues of cadavers dead from other diseases, neither allied nor similar to yellow fever.

5. The bacillus of Sanarelli, when subjected to agglutination tests, is not affected by the serum of yellow fever patients or convalescents.

6. The serum of convalescent yellow fever cases affords absolutely no protection against infection by the bacillus of Sanarelli.

7. None of the organisms thus far isolated from yellow fever cases can be considered as the pathogenic agent of the disease.

8. Experimental evidence has demonstrated that the serum of individuals convalescing from yellow fever, or who lately suffered an attack of this disease, will very materially and favorably affect those actually under the influence of the infection if injected under the skin, on or before the fourth day after the invasion; but that it requires further study to determine the protective power of different sera and the dosage.

9. From the experimental evidence above referred to, we are led to believe that the subcutaneous injection of convalescent's serum will convey immunity to individuals whom we to-day consider as susceptible to the disease.

Material for Research.—Material for research was obtained from cases of yellow fever during life at various stages of the disease; blood was drawn by pricking the ear-lobe for the purposes of planting and testing its clumping power, and from a vein at the elbow-joint; tissues and blood from various organs at autopsies were also obtained, some were planted, others were used in attempts at infecting animals. Later in our investigations we drew blood from convalescent yellow fever patients; serum was thus obtained

[3] Medical News, September 9, 1899.

with which to test its curative properties upon yellow fever cases and its protective power upon animals inoculated with some of the organisms derived from our cultures. A large number of cultures were made at the City Morgue from cases of sudden death, and some from necropsies other than of yellow fever cases.

Ear-Tip Blood.—The method of obtaining blood from the ear-tip for bacteriological research is one that is very generally and properly condemned; in spite of this fact, and the knowledge that the process is faulty and unreliable, we hour; after an interval of from six to eight hours this was plated. In some few instances we plated directly from the blood. From reading Drs. Wasdin and Geddings' "Report on the Cause of Yellow Fever," the writer is convinced that he washed off bacillus icteroides from the ear-lobe of every one of the following cases in which the "results" appear as copied directly from our notes. (See table I.)

From Nos. 4 and 20 we obtained a micro-organism very much like bacillus icteroides; its effect upon various culture media was identical

Table I.

No.	Name.	Age.	Date.	Day of Illness.	Result.
1	Th. B. Doane.....	52 yrs.	Jan. 9	4th.	Two non-pathogenic bacilli.

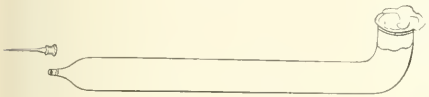
were induced to persevere upon its use by the rumor, lately confirmed, that Drs. Wasdin and Geddings, then engaged in the same work as the writer, were securing excellent results from it, isolating the bacillus icteroides in every case in which the blood was thus procured. Our method was to wash the lobe of the ear with alcohol and sterile absorbent cotton, pass the point of a lancet through the flame of an alcohol lamp, prick the ear with it, receive the issuing blood on the end of a sterile capillary glass tube, immediately sealing it at the flame; the two or three drops thus obtained were planted in bouillon within a half with that produced by this bacillus, but it gave large quantities of gas with saccharose and glucose bouillon and its pathogenic action was less intense than that of bacillus icteroides. Aside from these two cases, there was no one organism obtained from any of the others that required more than a cursory examination to determine its extraneous origin and none was sufficiently constant to deserve even the suspicion that it was at all related to the disease. From this we conclude that blood taken from the ear-tip, in spite of cleansing processes such as may be carried out at the patient's bed-side, is unfit for anything

more than microscopical examination or agglutination tests, that planting from such blood will in the majority of instances be contaminated, and that at all events the results thus obtained will always be open to doubt and adverse criticism.

Venous Blood.—The conviction of the worthlessness of ear-tip blood as material for research induced us to devise some means whereby to obtain blood during life in a manner that would preclude all probability of contamination. With this object in view we had made a number of glass tubes (Fig. 1) coming to a point with a

Fig. 1.



Instrument for Collecting Blood.

ground tip to which the platino-iridium needle is attached. The curved end is for the purpose of preventing the blood as it enters the horizontal tube from coming in contact with the cotton plug. The glass tube with its end cotton-plugged is sterilized, wrapped in gauze or filter paper. At the moment of using the needle is held by the point and the other end subjected to the flame of an alcohol lamp; the glass tube is unwrapped and the needle is fixed to the ground tip; the whole needle is then held in the flame until it becomes red hot, when we shall have a perfectly sterile tube from the point of the needle to the cotton plug in the curved glass tube. The bend of the elbow having been made surgically aseptic by the use of soap and water, bichloride solution and ether, pressure is made above while the needle is introduced into any of the superficial veins that will consequently swell up; once into the vein, the blood will readily flow through the needle into the glass tube and from one to six cubic centimeters may be thus collected.

The culture media may be carried to the bedside, or the blood safely taken into the laboratory and planted; one or two drops are allowed to fall into each tube. This method of securing aseptic blood has given uniform results in our hands. The pain inflicted is not greater than that produced by the ear-tip process and no greater care of the puncture is required, while the safeguards by which it is surrounded will necessarily inspire confidence in the results derived from its employment.

Out of a total of 281 agar tubes there were but 8 contaminated; of 25 milk plantings only one contamination, and of 49 bouillon tubes, 2 became contaminated. In not a single instance did the bacillus icteroides make its appearance. The organisms which developed in our culture media were thoroughly studied, with the following results: In case No. 4, one agar tube contaminated by staphylococcus pyogenes albus. In case No. 7, three agar tubes contaminated by a bacillus which liquefies gelatine; the same organism in all the tubes; 3 c.c. of a bouillon culture failed to kill a guinea-pig weighing 325 grams. In case No. 17, one milk and two agar tubes contaminated by a large non-liquefying micrococcus which produces endospores; subcutaneous injection developed abscesses, localized. In case No. 21, two bouillon and one agar tubes contaminated by mould. In case No. 27, one agar tube contaminated by mould, and a bacillus which forms filaments of unusual length, coagulates milk and renders a decided acid reaction to all culture media. None of the organisms obtained can be accused of being the causative agent of yellow fever. The result is disappointing, indeed, but such has been this investigation from the beginning; the only satisfaction that can be derived from it lies in the consciousness of its truth and a confidence in the methods employed.

Necropsies upon Yellow Fever Cadavers.—We believe that the history of each case autopsied, if detailed here, would make this report unnecessarily extended. The facts placed before each name in the following list will enable any one to verify them, if so inclined, by referring to the records of the Yellow Fever Hospital at Santiago de Cuba and Las Animas Hospital at Havana. Sections of tissues from all these cases were sent, from time to time, to the Curator of the Army Medical Museum, Washington, for study at the Pathological Laboratory of that institution. For the sake of brevity the notes made upon the pathological lesions encountered are also omitted; suffice it to say that the degree of

fatty degeneration of the liver was intense and "*black vomit*" was present in the stomach of *all* of them. Other lesions, also common to all, varied in the degree of their intensity; such were the heart infiltration, renal affection, engorged vessels, internal hemorrhages, icteric skin, etc. The disease in all these cases followed a typical course, as evidenced by its onset, development and the pathological lesions it produced (See table III.)

The first eleven cases occurred at Santiago de Cuba, the twelve that followed at Havana.

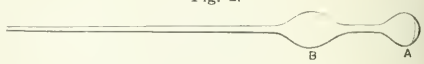
The conditions under which the autopsies were performed at Santiago de Cuba compelled us to refrain from attempting any cultures by the side of the cadaver and made it necessary to collect the material, in capillary glass tubes, and then take it into the laboratory tent, there to plant it in the culture media. For this purpose we made use of double-bulbed glass tubes (Fig. 2). After sterilizing the surface of the organ by means of a heated blade, the end of the capillary tube was broken off, passed through the flame, the bulb, *A*, heated and then the point introduced into the organ; by working the glass tube back and forth, considerable tissue and blood is made to enter into the bulb *B*, promoted by the cooling of the air in bulb *A*. When a sufficient amount is obtained, the end of the tube is sealed at the flame and the material is ready for planting. By having the double bulb, the material does not come in contact with the heated glass but remains at the first expansion in the tube.

Bacillus coli.—This organism, or rather some member of this group, was present in the cultures from every one of the autopsies above recorded. It was constantly found in the liver; in 8 cases (Nos. 1, 3, 4, 7, 9, 14, 21, 23) it occurred in cultures from the heart-blood; it was recognized in cultures from the kidney of 6 cases (Nos. 1, 2, 4, 5, 8, 20), the spleen of 4 cases (Nos. 4, 7, 11, 16), and the urine of three (Nos. 2, 9, 10).

Both motile and non-motile forms were isolated. The colon bacillus, like the majority of the organisms here described, must be one of the many invaders of the circulation at the last moments of the individual's life; we are led to this belief, not only because of the frequency of its presence, but more so from the fact that it was not found in the blood of patients during life.

Bacillus X (Sternberg).—Associated with the bacillus coli in a large number of cultures, its presence being recognized in some instances only after passing through guinea-pigs, was the bacillus X of Sternberg. This organism presented peculiar motility in some cultures while in others it occurred as a non-motile bacillus. It was classified principally from its pathogenic action on guinea-pigs which, when inoculated with pure cultures of bacillus coli, usually recovered; when these cultures contained bacillus X, a fatal result was the rule. It becomes deprived of its motility with great readiness, sometimes within a period of a few days. Passing

Fig. 2.



Double bulb for autopsy collections.

through susceptible animals will not restore locomotion. It is somewhat larger than the common colon bacillus; it stains readily by the aniline colors; retains the stain by Gram's method; grows easily in the ordinary culture media; does not liquefy gelatine. It is pathogenic to guinea-pigs and rabbits in intraperitoneal injections of from 1 c.c. to 3 c.c. of 24-hour bouillon culture. It was obtained in eleven autopsies, as follows: In the liver of six (Nos. 2, 3, 8, 11, 14 and 16); in the spleen of three (Nos. 2, 5 and 9); in the kidney of one (No. 17); in the urine of three (Nos. 15, 17 and 21) and in the blood of No. 13.

Drs. Wasdin and Geddings claim to have isolated this organism from the stools, urine and blood of a case of yellow fever,[1] but they add "called by Sternberg X, and by Archinard A and B." The two organisms referred to are as unlike as bacillus X and bacillus icteroides, and no one before has ever claimed their identity.

Bacillus pyocyaneus.—This organism, whose description we shall but briefly outline here, was obtained in cultures made from autopsies Nos. 1, 8, 14, 19, 20, 21, and 23. It is a short, motile bacillus; it grows in bouillon, potato, agar and

[1] Report on Cause of Yellow Fever, p. 16.

gelatine, liquefying this last medium in two or three days after planting. It gives to agar and gelatine, sometimes to potato, a light fluorescent greenish tint. Some of the organisms here classified as bacillus pyocyaneus may have been bacillus fluorescens liquefaciens (Sternberg), as no animal inoculations were undertaken except in two instances (Nos. 19 and 21). The organism was pathogenic to guinea-pigs and rabbits in subcutaneous injections of 0.5 c.c. or 1 c.c. of a 24-hour bouillon culture.

Bacillus icteroides (*Sanarelli*).—The bacillus icteroides occurred in seven autopsies out of twenty-three (Nos. 5, 6, 10, 11, 15, 16 and 23) making an average of 30.43 per cent. Its frequency in the organs was as follows: In cultures from the liver and heart-blood of No. 5; from the liver and spleen of No 6; from the liver and kidney of No. 10; from the kidney, blood and urine of No. 11; from the liver and pericardial fluid of No. 15; from the kidney of No. 16; from the liver and spleen of No. 23. Hence it will be seen that it was present in the liver of 5 cases, heart-blood of 2 cases, spleen of 2 cases, kidney of 3 cases and pericardial fluid of 1 case. We have been surprised at the comparative scarcity with which this organism has developed in our cultures, when, according to the report of the Marine Hospital Service Commission (Drs. Wasdin and Geddings), it was present at some time or other in the blood of all (14) cases of yellow fever that were examined, but one. Every one of our cultures was closely searched for evidences of this bacillus, and the methods we employed towards its discovery were those most highly approved of by bacteriologic technic. If we ever left a colony without thorough examination or classification, it was because we found it composed of micrococci or non-motile bacilli; while on the other hand much time was spent upon motile bacilli which at all resembled in their cultural characteristics the bacillus icteroides That this organism is not to be found in yellow fever as frequently as Drs. Wasdin and Geddings would have us believe is shown by the evidence of Sanarelli's own supporters, Drs. De Lacerda and Ramos,[1] who vainly sought for it during last winter's epidemic in Rio de Janeiro. They say: "*Mais il faut dire, avant cela, que l'un de nous (M. Ramos) a fait des tentatives réitérées dans le but d'isoler du cadavre le bacille de Sanarelli, sans y réussir.*"

These gentlemen have found decided discrepancies between Sanarelli's description of the organism, and the way it has behaved in their hands; in the article referred to above, they say (p. 384): "*Malgré toute notre bonne volonté, il faut bien dire, nous n'avons pas pu trouver cette forme, dite spécifique, des colonies, dans un nombre assez grand de cultures, soit en gelatine, soit en gélose.*" Sanarelli pretends to explain this by claiming unusual "pléomorphisme" for bacillus icteroides.

[1] "Le Bacille Icteroide et sa Toxine," Arch. de Med. Exper. et d'Anat. Path., Vol. XI., No. 3, May, 1899.

The organism which we isolated from these autopsies is a small bacillus that stains readily with the ordinary stains and gives up the color with Gram's method. It is motile, aerobic (facultative anaerobe), and grows in the usual culture media, producing gas in glucose bouillon. It is pathogenic to guinea-pigs in subcutaneous injections of from 0.3 c.c. to 1 c.c. and also to rabbits and dogs, the latter dying from an intravenous inoculation of 6 c.c. The lesions it produces are such as are found with many other organisms; now and then, in the liver of guinea-pigs, we have observed the focal necroses first described by Dr. Reed of the Army Medical Museum Laboratory, Washington, D. C. We have not engaged in experiments to ascertain its connection with the hog-cholera bacillus. That a close relation between them must exist is made evident by the researches of Reed and Carroll.[1] Bacillus icteroides was isolated by us in 33.33 per cent. of the cases examined at Santiago de Cuba in the summer of 1898.[2]

Bacillus acidiformans.—This was present in autopsies Nos. 12, 20 and 21; obtained in cultures from the livers of these cases. It is a non-motile, rather large bacillus; it quickly acidifies the culture media forming gas bubbles in gelatine stick cultures. It had a decided action upon litmus milk, a heavy growth on agar slants; its pathogenic power was not determined.

Staphylococcus pyogenes aureus.—This occurred in cultures from the liver of autopsy No. 3, but has not been met with in any other examination.

Staphylococcus pyogenes albus.—This was obtained in cultures from the liver of case No. 12. It has frequently occurred as a contamination from the surface of the body or from the air.

Chromogenic bacteria from air contamination were also found.

Anaerobic cultures were made exclusively from some of the Havana autopsies; particularly from cases Nos. 14, 16, 17, 21 and 22.

The method employed has generally been the substitution of the air in the culture tube and media by hydrogen gas, then sealing the test tube at the blow-pipe. In this manner several growths have been developed; nearly all of them were identified with like organisms in our aerobic cultures, while only two bacilli developed that may be said to have been strict anaerobes: one of them was undoubtedly the *bacillus cadaveris of Sternberg*. This was present in cultures from the livers of autopsies Nos. 14 and 21. The growth was obtained in plain-agar slants and stick cultures. The organism isolated was afterwards cultivated in glycerine agar (2 per cent). A subcutaneous injection proved fatal to three guinea-pigs. Two others injected with the same organism recovered.

A Sporulating Bacillus.—This was present in the liver of No. 21. The original growth was

[1] Medical News, September 9, 1899.
[2] Author's Report, December, 1898.

obtained in a plain-agar tube stick culture, treated as above outlined. It developed alongside of bacillus cadaveris, producing whiter and less granular growth. It is larger and more slender than bacillus cadaveris, and forms spores which resist the action of 80° C. for thirty minutes. It is non-motile and strictly anaerobic. It is apparently non-pathogenic, its subcutaneous injection of guinea-pigs produce edema and abscess with very foul odor.

Autopsies upon Other Than Yellow-Fever Cadavers.

As mentioned in the beginning of this report, the writer endeavored to obtain permission to perform autopsies upon cases dead from other diseases than yellow fever, but the amount of work which came upon us at the early part of the summer very materially prevented the possibility of research in other channels. As it is, numerous cultures were made at the city morgue from cases of sudden death. Some of the bodies were allowed to remain on the table for too long a period of time to be of any use as bacteriological material, but in most instances the autopsy was made a few hours after death. The number of organisms isolated is greater than we would care to even outline here and as the work was undertaken for the sole purpose of finding bacillus icteroides, if present, no time was wasted upon any single species that showed the slightest discrepancy with any of the well-known characteristics of this organism. It was present in one of them. Besides the sudden death cases, cultures were made from eight other autopsies; the bacillus icteroides of Sanarelli was found in two of them, making in all three cases in which there was not the barest possibility of yellow fever infection.

They were as follows:

February 13, 1899.—At the city morgue, the body of a white man about thirty years of age, had died as a result of stab wound of the abdomen. Upon opening the peritoneal cavity it was found to contain a large quantity of purulent serum, the intestines being matted together with plastic exudate. Cultures were made from the liver and spleen only, upon six agar slants. On the following day three tubes were discarded, the degree of contamination did not warrant the time that would be required in isolation and classification; from the other cultures, two from the liver and one from the spleen, three organisms were plainly isolated: (1) Bacillus coli communis, (2) bacillus icteroides, and (3) staphylococcus aureus. The patient was a native and had been perfectly well until two days before, when he was stabbed.

February 15, 1899.—Patrick Smith, private, Company B., 8th U. S. Infantry, died at 11 A. M. The autopsy was performed by the writer at 1:30 P. M., in the presence of Drs. Wasdin, Geddings and Menocal of the Marine Hospital Service, Majors Gorgas, Davis and Ducker of the Army, Assistant Surgeon Truby, who treated the man during his illness, Dr. Porto, director of the city morgue, where the autopsy was made, and Drs. Cordova, Carvallo and Castro, the last two gentlemen being the coroners on duty at the time. Patrick Smith was admitted to the Regimental Hospital at La Punta on February 4th, complaining of having felt sick for about a week, which he attributed to malaria, having suffered from this disease in Santiago the previous summer; he was quite anemic, there was some albumin in the urine, the temperature kept around 103° F., the pulse was always high, above 100 beats per minute. During his illness he had liquid stools, yellow, and marked adynamia; no vomiting took place nor was there any epigastric tenderness except upon forcible pressure. We saw the case for the first time on the morning of the 10th, as it was suspected that he was suffering from yellow fever; on the 11th we took blood from the ear-tip and planted it with the results already mentioned above. (See ear-tip blood.) We again saw the patient on the 12th and every day afterwards until his death, eleven days after admission to the hospital. We never believed the man had yellow fever, although we admitted that the case was obscure until later, when we learned that there was a slight epidemic of typhoid fever in Company B.

We take special pains in describing this case, because in the "Report on the Cause of Yellow Fever" Drs. Wasdin and Geddings give this as a typical (!) yellow fever case of "serious type and prognosed death within forty-eight hours" (loc. cit., p. 14), which prognosis was realized five days afterwards.

The lesions encountered were as follows (taken from our notes): The body was emaciated, and its color that of the cadaver of anemic individuals; the gums were pale, the sclerotics had a slight yellowish tint. There were hypostatic congestions on the neck, trunk and extremities; on section, the tissues were found very dry. The liver was very much enlarged, of a purplish hue, with a hard, glistening, smooth surface, and absolutely no evidence of fatty degeneration, a congested hyperplastic liver such as is found in autopsies upon chronic malarial cases. The cut surfaces were smooth and bled freely. The spleen was the size of a man's head, hard, congested, of an ashy-blue color. If these two lesions alone had been met with, the case would have been declared a victim of the malarial parasite; they were typical, except for the great extent to which the organs were involved. The stomach was slightly dilated; the mesenteric vessels rather full; it contained absolutely nothing but undigested food (milk) and mucus; the mucous membrane was pale except at the posterior surface, where there was some hypostatic congestion; it was also edematous and easily torn in manipulation; there was no submucous extravasation nor any sign of any vascular disintegration. The duodenum contained the same liquid food; the mucous membrane was pale, except at

the dependent portion where there occurred hypostatic congestions. The small intestine was examined throughout its whole length, at its lower portion it contained semi-solid fecal matter of a pale-yellow color. At short and regular intervals, corresponding with the intestinal coils, there were areas of hypostatic congestion which were thought by some one present to have been submucous extravasations, but upon section were found to be as above stated, purely congestive areas which probably began to form long before the patient's death, he having been in an adynamic condition for several day previous to the fatal termination of his disease. The mucous membrane was puffy and particularly near the ileocecal valve; Peyer's patches, although visible, cannot be said to have been enlarged; there were a few swollen mesenteric glands in this region.

The colon contained the same pale-yellow feces, and aside from a friable eroded mucous membrane showed no other lesion of apparent importance. From the esophagus to the anus no evidence of the slightest free hemorrhage was encountered. The kidney was slightly enlarged and congested, the seat of a subacute interstitial nephritis. The capsule was not adherent. The pericardium contained a small amount of serous fluid. The heart contained much blood, the walls were rather soft, but there were no evidences of fatty degeneration. No engorgement of its vessels was present, the vasa vasorum at the base were not enlarged; the endocardium was normal; a weak heart and nothing else. The lungs were somewhat edematous and presented hypostatic congestion posteriorly. A diagnosis of anything else than yellow fever could have been made from the findings at this autopsy; none of the gentlemen present, except the representatives of the Marine Hospital Service, with the evidence placed before them, had any doubt in this regard; Dr. Wasdin insisted that the lesions of the intestines were extravasations and not hypostases; Dr. Geddings was doubtful; Dr. Menocal said nothing.

Our opinion was that the man had died of an enterosepsis of undetermined character, very materially aided by a chronic malarial infection, and that the bacteriological cultures would undoubtedly throw some light on the actual cause of death.

At the risk of lengthening this report to a tiresome extent, we beg to quote from the evidence of some of the gentlemen who saw the patient during his illness and at the post-mortem.

Lieut. A. E. Truby, Assistant Surgeon, U. S. Army, was in charge of the case at the Regimental Hospital; he writes us: "In my opinion he (Patrick Smith) did not have yellow fever. He had a marked amount of albumin in the urine, present from the beginning to the end of his sickness and in about the same proportion. He had been a sufferer from chronic malaria since the campaign in Santiago. During his last spell of sickness he had all the signs and symptoms of typhoid fever. Another case from the same Company died on the hospital ship "Missouri;" the autopsy showed marked typhoid ulcers and evidences of chronic malaria. The symptoms in both cases were the same. In all cases of typhoid fever in men who have been in this hospital, who were still suffering from the chronic malaria contracted in Santiago, we have found albuminuria. Smith had a pulse rate above 100 per minute throughout, and a temperature ranging around 103° F."

Major W. C. Gorgas, Surgeon U. S. Army, writes: "I observed P. Smith, 8th Inf., for about a week before he died. During his life I considered the case suspicious with possibilities in favor of yellow fever. At the autopsy I was convinced that the case was not yellow fever. I saw nothing in any of the organs that resembled yellow fever. There have been quite a number of cases of typhoid fever from this Company, two of them presenting symptoms very much like Smith's. Seven of ten medical men present at the autopsy gave their opinion against yellow fever."

Major Orlando Ducker, Surgeon, U. S. V., writes: "I first saw the case, with Major J. G. Davis, on February 9th, 1899 . . . . it was then the 8th day of the soldier's illness. Temperature 103.5° F.; pulse, 132; respirations, 29. My diagnosis was pernicious malaria with typhoid complications . . . . I saw the case two or three days later; there had been no change; temperature 102.5° F.; pulse, 124; respirations, 28. There was increased tympanites, increased sensitiveness over the bowel, but not so over the duodenum. The yellow tinge of the skin not so deep. A few days thereafter, I was present when you made the autopsy. The skin was less yellow than during illness . . . . I believe had the patient lived a few days longer, there would have been sloughing and perforation of the bowel. The liver was a typical malarial one, there was no yellowish or steel-colored hue. From the history of the case and from examination as well as from autopsy, I can make no other diagnosis than pernicious malaria with typhoid complications and I believe these two were the sole cause of death."

Dr. E. M. Porto, Director of the City Morgue, writes: "Neither from the color of the body, so characteristic in yellow-fever cadavers, nor from the pathological lesions found, could I suspect for a moment that we were dealing with a yellow-fever case; the predominating hyperplasia of liver and spleen indicated a malarial infection." (Translation.)

Dr. S. de Castro, one of the coroners on duty, writes: "I am inclined against the case being yellow fever; it lacked the icteric tint and the hemorrhages or blood infiltrations of stomach and small intestine. The spleen and liver indicated paludism." (Translation.)

Dr. Frederico Cordova also believes the lesions were mainly malarial; he writes: "The color of the skin was not of that distinct yellow which is found in yellow-fever cases, neither did the liver

by its dark color and firm consistency have any similarity with the changes regularly found in that disease; there was also total absence of the hemorrhagic extravasations so typical in yellow fever." (Translation.)

Microscopic examination of the blood made on February 11th, at the Laboratorio Histo-Bacteriologico revealed the presence of malarial parasites and pigmented leucocytes.

We found bacillus typhosus and bacillus icteroides in almost pure cultures from the spleen; bacillus typhosus in pure culture from the kidney; colon bacilli; bacillus icteroides and a non-motile bacillus from the blood of the bacillus only from the blood of the heart. With regard to the presence of bacillus icteroides and the influence it may have exerted in this case, we beg to refer to the "Report on the Cause of Yellow Fever;" it says: "At this visit (February 10th) blood was taken from the ear-tip (on the sixth day of the disease), and when plated gave us numerous colonies of bacillus icteroides" . . . (page 14). "On the 12th from the blood taken a serum test was made in the dilution of 1 to 20, with a bouillon culture of bacillus icteroides and there was not the slightest influence of either motion or agglutination in three hours. Nor could we get a reaction at any time. This organism we have used very extensively in further work on animals, the resulting necropsies always showing the most characteristic changes in the liver, stomach and intestines."

From the above paragraphs it will be seen that it is claimed that bacillus icteroides was present in large quantities in the blood of the patient on the sixth day, yet on the eight day it fails to be influenced by the serum of this same individual, even after three hours (!) when normal serum would certainly tend to, at least temporarily, immobilize or agglutinate bacillus icteroides. This confirms us in our belief that bacillus icteroides, if present in the blood of Patrick Smith as early as claimed by Wasdin and Geddins, did not exert any influence upon the severer typhoid-malarial symbiosis from which he was suffering. Bacillus icteroides in this instance ran hand-in-hand with the colon bacillus and the other microorganisms that were isolated.

July 14, 1890.—Benjamin Goodman, civilian, twenty-three (?) years of age, died at 1 P. M.; autopsy at 5 P. M. The man had been suffering from rheumatism for over a month; was treated for malaria up to one week before his death; lately he had dysentery and had been prostrated in his store in Santiago de Cuba, unable to attend to his business (saloon-keeper); he had not had medical attention for three days, when he was found in a dying condition in his room. The city being at the time strictly under quarantine, the body was taken to the Yellow Fever Hospital for the purpose of ascertaining the cause of death.

On autopsy, it presented the following, taken from our notes: "The body is that of a man about forty-five years of age, in rigor mortis, very pale, there is much abdominal fat; hypostatic congestion on the dependent portions. There is no icterus. The mesentery also contains much adipose tissue. The liver is large, of a dark, mottled ashy-brown color, the surface very rough, cirrhotic, with areas of fatty degeneration; cut surfaces granular and moist; the liver of chronic alcoholism. The spleen is of normal size, congested. The stomach is very much dilated, to three times its normal size, the walls are very thick; it contains a large quantity of clear gastric juice and mucus; the mucous membrane is thickened, edematous; the peptic glands are inflamed and enlarged. The duodenum is congested, and contains a small amount of bile. The small intestine is generally inflamed, the seat of an acute enteritis. The colon contains liquid feces; the mucous membrane is swollen and eroded, particularly at the descending portion. Some mesenteric glands were enlarged. The kidney is the seat of a chronic parenchymatous nephritis; the capsule is adherent. The abdominal cavity contains a quantity of serous effusion. The pericardium is tough and contains a small amount of serum. The heart is very much hypertrophied, but soft and in diastole; it contains very little blood. The endocardium is roughened by vegetations; there are calcareous deposits in the auriculoventricular and aortic valves and retraction and insufficiency of the mitral and aortic. The aorta is in an atheromatous condition. The lungs are edematous, on section giving large quantity of serous fluid. The pleuræ are smooth and apparently normal.

Cultures made from the liver of this case developed bacillus icteroides in company with bacillus coli, and a pathogenic variety which was accidently sterilized and could not be studied further.

The three cases above described *were not yellow-fever cases*, and we offer them in refutation to the statement made that bacillus icteroides is not found except in yellow fever.

(To be continued.)

CLINICAL MEMORANDUM.

ATRESIA VAGINÆ; SOLID UTERUS; HEMATOMA OF LEFT OVARY.

BY H. J. GARRIGUES, M.D.,
OF NEW YORK;
GYNECOLOGIST TO ST. MARK'S HOSPITAL.

M. B., American, twenty years of age. Has never menstruated. Every four weeks for the last four years she has had severe pain radiating from the back, around the abdomen to the hypogastric region, lasting a week. Epileptic convulsions, with complete loss of consciousness, foaming at the mouth, and biting the tongue, preceded and often followed the molimina. The patient's intelligence has suffered, as evinced by slowness in answering questions.

Vaginal examination showed a normal vulva

and a vagina two inches deep, without communication with the uterus. Between the vagina and the cervix there was half an inch of soft tissue. Above that was felt a large, round mass in which a hard and soft portion could be distinguished. On account of her epileptic seizures and impaired intelligence, and because such an attempt had been made in vain by another gynecologist, I desisted from trying to make a vaginal connection.

Laparotomy (October 25, 1899) revealed a uterus of about normal size and shape, but a little thick in the antero-posterior diameter. The right ovary was slightly enlarged, and showed a fresh corpus luteum filled with blood. The right tube was normal. The left tube was thickened and bound to a large cyst, which nearly filled the pelvis and was adherent to its walls and to the intestine. I removed the uterus, right tube and ovary in one piece by supravaginal amputation, and then extirpated the cyst. This proved to be the left ovary changed into a hematoma, containing ten ounces of inspissated, chocolate-colored blood.

After the operation the patient suffered much from insomnia and had some pain in the left side of the pelvis, where a small swelling was felt around the stump of the infundibulo-pelvic ligament. She had a slight rise in temperature. On November 11th—seventeen days after the operation—according to the statement of the house-surgeon, three pints of old blood were evacuated through the vagina, at the top of which was felt a small opening. A sound entered through it into a large cavity extending in the direction of the right iliac fossa, where she had some pain. The fluid coming from the opening was old blood mixed with a small amount of pus. I dilated the opening under ether and introduced a double drainage-tube with cross-bar. The patient has been entirely relieved of her molimina, but has had several epileptic seizures during her stay in the hospital and after leaving it.

After being emptied, the sac formed by the ovary contracted to the size of a hen's egg, showing what an enormous pressure the bloody contents had been under. The inspection of the inside of the tubes showed a normal mucous membrane. The wall of the left tube was thickened. The uterus had no trace of a canal.

A solid uterus of normal size and shape is very rare, perhaps unique. As a rule this condition is only found when the uterus is represented by a more or less formless mass, and even such rudimentary uteri are extremely rare.

The large hematoma must be looked upon as an internal vicarious menstruation. There being no uterine cavity, the menstrual congestion must have found a weak point in the left ovary, and during four years blood had accumulated in it, transforming it to a bag, which nearly filled the cavity of the pelvis.

716 Lexington avenue.

MEDICAL PROGRESS.

Mucinemia in Thyroprivia.—In order to determine the nature of the substance which causes the autointoxication in cases where the thyroid gland is absent (myxedema, cretinism) or where it has been removed by operation, I. Levin (*Med. Record*, Feb. 3, 1900) has made several experiments on rabbits. Believing that the accumulation of mucin in the blood explains, to a great extent, at least, the symptoms of this condition he injected a solution of mucin in one-per-cent. sodium carbonate into eight normal and nine thyroidectomied rabbits. The former remained healthy while only one of the latter survived. It was also shown experimentally that much in-

jected into the blood of a dog uniformly caused a fall of blood pressure.

Surgery of Typhoid Perforations.—W. W. Keen (*Jour. Am. Med. Assoc.*, Jan. 20, 1900) says that operation is the procedure of choice in treating typhoid perforation, except in the few patients whose condition is such that recovery is hopeless. Patients have been operated on three times and yet recovered. Age seems to affect the recovery-rate. Thirteen under fifteen years of age gave nearly 54 per cent. recoveries; 43 from 15 to 25 years of age, 9.3 per cent.; 43, 25 to 35 years of age, 23 per cent., and 20 cases over 35 years, 30 per cent. The female sex has a higher percentage recovery, 42 per cent. in 20 cases, whereas in 106 male cases only 18 per cent. recovered. Perforation in the fourth week has given 33 per cent. recovery, while in the third week only 16 per cent. recover. The best time to operate is as soon as possible after perforation, but not during profound shock. The statistics show that operation during the second twelve hours has given the best results up to this time. While waiting for reaction from shock peritoneal infection is increasing. The avoidance of both these evils depends on advance in two directions, the possible diagnosis of impending perforation, and exploratory operation under cocaine. The use of cocaine instead of a general anesthetic is the most important recent advance in technic. The incision under cocaine is best made in the right linea semilunaris or through the rectus. The perforation should be sought in the ileum, in the cecum and appendix, or in the sigmoid. The perforation should be closed, without paring the edges, by a mattress suture, and if necessary, with a superimposed continuous suture. Thinned areas threatening to perforate should be inverted and sutured. With extensive or adjacent perforations resection and anastomosis may be required. Drainage is usually required, but if the case is not of too long standing and the peritoneum can be well cleansed, it is better to fill the cavity with salt solution and close without drainage. Speed is important, but not at the expense of careful work.

Syphilis from Dental Instruments.—Wm. L. Baum (*Jour. Am. Med. Assoc.*, Jan. 27, 1900) reports six cases of syphilis, in five of which the infection is attributed to wounds from dental instruments, and in the sixth case to an instrument (tonsillitome) in the hands of a physician who never boiled his instruments. He divides syphilitic manifestations in the mouth into three kinds: (1) The initial lesion, or chancre, which may appear on the lips, tongue, tonsils, or fauces; (2) secondary lesions, such as erythematous or papular syphilides, which occur on the velum, the palate and the tongue; (3) tertiary symptoms, such as gumma, which may attack the tonsils, uvula, soft palate, or tongue. The writer gives a description of the different lesions as they appear when found in the mouth. All dentists should have a knowledge of the characteristic appearance of the different syphilitic lesions and should also make a practise of boiling all their instruments.

Use and Abuse of Poultices.—The injudicious employment of the poultice has brought it into such general disrepute that its benefits are now oftentimes lost sight of and its use discarded. S. E. Earp (*N. Y. Med. Jour.*, Feb. 3, 1900) points out that the active principles of the poultice are moisture and heat and hence it matters little what they consist of except so far as their capability of retaining heat is concerned. They must be generous in size, applied hot, and frequently changed. In general it is better to use antiseptic fomentations upon open wounds, but the charcoal poultice is of considerable value as a deodorant in some cases of foul ulcer. The virtues of a poultice are seen in its power (1) to relieve congestion, (2) to promote absorption, favor resolution and hasten suppuration, (3) to diminish tension, (4) to soften incrustations, (5) to stimulate healthy granulations and (6) to perform the office of a deodorant.

Laryngeal Complications of Typhoid.—Peculiar affections of the larynx during the course of typhoid fever have been reported rarely and have been classed as (1) edematous laryngitis, (2) ulcerative laryngitis and (3) laryngeal perichondritis. R. M. Marsden (*Med. Chronicle*, Jan., 1900) has described three cases, one of which belongs to the first class, the other two ending as a perichondritis, which may have been secondary to ulceration. The peculiarities of the cases were that they came on late in the disease, with trivial symptoms of cough and hoarseness until the disease was far advanced, with no discharge of pus or cartilage, but resulting in such marked thickening in and around the vocal cords that the obstruction demanded tracheotomy in each case. The after-treatment of persistent and systematic dilatation was tried with only slight success, the fixation of the cords preventing much improvement in phonation. Where the arytenoids and cords are movable and when a cannula has been introduced, the patient can speak with a fair voice, it is well to persevere with dilatation.

Nephrolithiasis treated with Glycerin.—In the *Medical Chronicle* (January, 1900) A. Hermann reports the use of glycerin in 115 cases of nephrolithiasis with favorable results in 60 per cent. of the patients so treated. In 15 cases concretions were passed with improvement of symptoms while in 25 cases alleviation of symptoms occurred without the passage of any concretions. In order to explain the favorable action of glycerin it is supposed that the effect is physical rather than chemical since no solvent action can be demonstrated. In addition to acting as a lubricant to the urinary passages, it increases the specific gravity and viscosity of the urine and tends to change the position of the concretions in the pelvis of the kidney. The dehydrating power of glycerin is pointed out as a cause for the voiding of quantities of pus and mucus after its administration. The dose is from one to four ounces dissolved in an equal amount

of water and taken between two meals and repeated two or three times in an interval of several days.

Seasickness.—Seasickness is defined by J. Carlisle De Vries (*Indian Med. Record,* Calcutta, Dec. 27, 1899) as "a peculiar functional disturbance of the nervous system, produced by shock resulting from the motion of the ship." He does not consider it a disease of the stomach or alimentary canal, but clearly a functional disease of the central nervous system. The disturbance is divided by him into four stages, *viz.,* depression, exhaustion, reaction, and convalescence. The symptoms begin with a general depression followed by giddiness, nausea, vomiting, and derangements of the bowels and urinary secretion. An abnormal appetite often precedes the stage of depression. As to the treatment, sometimes a deep inspiration simultaneous with the rise of the vessel, followed by expiration as it descends, will ward off seasickness. The writer has not seen any good results from bromide treatment. To lessen the likelihood of an attack the bowels must be opened the day before embarking by calomel, sodium phosphate, or a saline purge, and about twenty grains of sodium bromide taken at about 7 A. M. the day of sailing. One should remain on deck throughout the voyage and partake freely of mineral waters. When one has not taken this preliminary treatment aromatic drinks, lemonade, champagne, and ginger ale prove of great value. A horizontal position should be maintained, and a general plain diet, but no cold food should be taken. Give brandy or wine if stimulation is needed. If confined to stateroom a spinal ice-bag relieves the spinal congestion. In obstinate cases nitrate of amyl given in full doses on the first appearance of epigastric distress is beneficial. When everything else fails, morphine may be given to relieve the retching, but should be given carefully. The writer's experience was gained in 58 transatlantic voyages.

Indigestion and Pulmonary Disease.—Under normal conditions the small intestine is practically free from micro-organisms, while the large intestine is not. After a brief summary of what occurs in normal digestion C. R. Burr (*Bost. Med. and Surg. Jour.,* Feb. 1, 1900) says that it is evident that autointoxication may result, if a departure from the normal occurs in either the intestinal tract or the liver. If indigestion occurs in the intestinal tract the small intestine becomes a veritable culture tube for micro-organisms, and they and their products pass to the liver along with other imperfect products of intestinal and gastric digestion. The result is that the liver-cells are poisoned and do not perform their duty, and as a consequence the general circulation is flooded with poisons, and autointoxication is established. Again, if a person has an insufficient, or functionally weak liver, which often fails in its duties and permits an undue leakage from the portal to the hepatic vein, the same condition of autointoxication will obtain. The blood purifies itself through the skin, lungs, and kidneys, the vehicles being the sweat, the breath and urine. If a case of toxemia is severe enough all these eliminating organs may present acute symptoms. In the lungs, congestion, edema, pneumonia, or bronchitis occurs. The changes in these organs are more chronic in character if the toxemia is less severe, but longer continued. Few organs of the body escape the effects of a general toxemia, but in addition to the three organs mentioned the nervous system and the blood seem to suffer the most. A condition of hemoglobinuria develops in the blood, and organic changes may occur in the nervous system if the toxemia lasts long enough. The medulla and the nerves issuing from it are especially affected by toxalbumins. One of these nerves is the pneumogastric, which is intimately associated with the respiratory center. The writer has already pointed out that there is a paresis of both the phrenic and pneumogastric nerves in pulmonary tuberculosis. In short, repiration may be embarrassed by toxalbumins as well as toxins and ptomaines, no matter how introduced into the system. The action of the diaphragm being interfered with, the capillaries are not emptied and a condition of stasis ensues. Because of this stasis the excrementitious principles carried by the venous blood weaken or paralyze the epithelial cells of the pulmonary alveoli and the endothelial cells of the capillaries, so that they do not repel microbic infection from without. The writer cites a case showing how the lungs can be infected from within. In this case the typhoid bacilli went from an infected intestine, through a paretic liver, into the general circulation, and thence to the lungs. Thus autointoxication arising from simple intestinal indigestion affects the lungs so that they not only cannot repel microbic infection from without or within, but rather invite it.

In croupous pneumonia the coagulation necrosis is limited to the epithelial lining of the alveoli, therefore, it would seem that the epithelial cells were first infected, that is, that the bacteria were inhaled. On the other hand, the coagulation necrosis of pulmonary tuberculosis attacks the capillary network of the lung. The exudate occurs on the outside of the alveoli. The bacteria, therefore, come to the capillaries by way of the general circulation and in many cases without doubt from an infected intestine. With these facts before one Burr thinks some changes might be advantageously made in the traditional treatment of pneumonia and pulmonary tuberculosis. In these diseases great care should be given to the condition of the digestive tract. The intestines should be evacuated and disinfected. Intestinal alteratives are indicated, and no drugs are better than calomel and podophylin. They are best given in small and repeated doses. The inhalation or ingestion of oxygen is of great value. In pneumonia in the first stage, that of hyperemia of the capillaries, the writer uses, as an astringent to contract the capillaries, the soluble phosphate of iron in small and repeated

doses. Tincture of aconite seems to aid it. When hepatization has occurred sodium chloride and pancreatin hasten the digestion of the pneumonic exudate. The writer injects a pint of normal salt solution with a few grains of pancreatin in it, well up into the sigmoid flexure. The sodium chloride exerts an antiseptic influence and the pancreatin may assist in the digestion of the pulmonary exudate. Fresh air and the cure of intestinal indigestion will do much to improve the condition of a patient with pulmonary tuberculosis, and if begun early enough a cure in some cases may result.

Carcinoma of Ascending Colon.—W. McA. Eccles (*Brit. Med. Jour.*, Jan. 13, 1900) records two cases of carcinoma in this comparatively rare site. The first case entered the hospital suffering from acute intestinal obstruction. A median exploratory incision revealed an annular carcinoma of the ascending colon. Through an incision in the linea semilunaris the growth was excised and an artificial anus established in the wound. Death resulted from shock. In the second patient a moveable tumor was felt in the right side. The growth and considerable colon on each side of it were lifted out into the abdomen and prevented from slipping back by sutures placed in the deeper parts of the wound, which was then partially closed, sterile dressings applied, and the patient returned to bed. Fecal circulation continued through the extra-abdominal colon without difficulty. On the eight day, without an anesthetic, the growth was excised and end-to-end anastomosis done, extraperitoneally. The gut healed and gradually retracted into the original wound, and recovery occurred without incident. Success in colectomy depends upon operating before acute obstruction occurs. When there is sufficient mobility, eventration followed by later excision is the safest procedure. If there is acute obstruction, eventration with formation of an artificial anus relieves the immediate symptoms and avoids adding the shock of colectomy to that of the obstruction. The growth can be excised at any later time without an anesthetic. Where the growth is fixed to the parietes, the best procedure is to carry the fecal circulation around it by an ileocolic anastomosis.

Gastrectomy.—G. C. MacDonald (*Phila. Med. Jour.*, Feb. 3, 1900) says that no operation requires more careful selection of cases, and more careful preparation for the strain and shock of operation. The patient must be neither very old, thin, nor cachectic. The heart especially must be in good condition. Patients who have used alcohol even to slight excess, and those who have been subjected to constant nervous strain are not suitable. Renal or hepatic disease contraindicates the operation. The stomach should be made as nearly aseptic as possible. The operating-room should not be cooler than 80° F., the patient should be swathed in cotton and placed on hot-water bags to prevent loss of heat. At least four trained assistants are necessary to the rapid, smooth performance of the operation. The stomach is exposed through a long median incision, its attachments divided from cardia to pylorus, and it is then resected. The esophagus and duodenum are then joined by a Murphy button, or if the cut ends cannot be easily approximated, the duodenum is closed, and the esophagus anastomosed with a convenient portion of jejunum. The wound is then closed and the patient put to bed, which must be well warmed. Since both vagi are cut and the solar plexus much handled, marked nervous disturbances occur; there is considerable shock, and the heart gallops because of the uncontrolled action of the sympathetic. Besides the general stimulation for shock, one must steady the heart's action by digitalis as otherwise it stops work inside of three days from sheer exhaustion. After twenty-four hours liquids may be given by mouth, and as soon as the button is passed, solid food may be given. The causes of failure have been: Poor general condition, the patient dying either on the table or soon after operation; the heart has galloped to exhaustion in spite of treatment and leakage and peritonitis from imperfect coaptation of esophagus and duodenum.

Treatment of Neurasthenia.—The close contact of physician with patient is of extreme importance in the cure of neurasthenia according to O. Dornblüth (*Münch. med. Woch.*, Jan. 16, 1900). A thorough physical examination will awaken confidence and prevent errors of diagnosis and the patient should be informed of the true character of his disorder. The most important rules to keep the patient in bed and absolutely at rest for from one to six weeks, depending on the severity of the case. Where this is impossible, the recumbent posture should be assumed during all leisure moments. Strict dieting is not necessary; even coffee and tea may be allowed, but alcohol is to be strictly interdicted. Even when nervous dyspepsia is present the regular plan of feeding five times daily at intervals of two and a half to three hours is admissible, but when great irritability of the stomach dominates the clinical picture, the diet should be similar to that for gastric ulcer, or solid and liquid food alternately every one and a half hours may be given. To quiet the nervous system the best results were obtained by applying cloths wrung out in water at 59° F. to the abdomen and covering these with flannel, or by giving a bath at 81-88° F. with the tub but half filled, for four minutes. Massage is not to be resorted to but general faradization with weak currents is excellent. As for drugs, a depreciated condition of the blood demands iron, preferably in organic form, while for the severer manifestations of the disease codeine acts almost as a specific. In selecting sanatoria, especial care is necessary to choose such which really meet the indications.

Diagnosis of Gastric Ulcer.—F. H. Murdoch (*Phila. Med. Jour.*, Feb. 3, 1900) says that the most important point in the diagnosis of gastric ulcer is to think of ulcer. He reviews the symp-

toms of the disease and cites some cases. Hemorrhage and the peculiar epigastric pain are the most important. He lays special stress on the importance of the circumscribed tender spots found in front over the stomach and the corresponding tender spot in the back to the left of the twelfth dorsal vertebra. He says that if, in a patient with dyspeptic symptoms, a small circumscribed spot of tenderness in the epigastrium is found it is justifiable to make a diagnosis of gastric ulcer, whether there has been pain or hemorrhage or not. This tender spot, however, must be constant, not present one day and absent the next. This tenderness lasts for months sometimes and it is not safe to give solid food while it is present. General tenderness over the stomach is uncommon.

Orthoform promptly relieves the pain of gastric ulcer and because of this is a valuable aid in making a diagnosis. The writer concludes that in patients with dyspeptic symptoms, gastric ulcer may be diagnosticated positively in one of three ways: (1) By the occurrence of hemorrhage from the stomach; (2) by the presence of severe pain relieved by orthoform; (3) by discovering a small, constant, circumscribed spot of tenderness in the epigastrium with or without a corresponding tender spot to the left of one of the lower dorsal vertebræ.

Acute Serous Synovitis.—P. Hoffmann (*N. Y. Med. Jour.*, Jan. 27, 1900) speaks of the compression treatment of acute serous synovitis. The principle is to fill all depressions about the joint with cotton and then obtain firm, even pressure by means of adhesive plaster strips, which should extend several inches in each direction from the joint. The absorption of the effusion is very rapidly accomplished and at the end of the first day the dressing must be renewed on this account. Flexion, which is usually present where the effusion is considerable, rapidly disappears. The other advantages of the treatment consist in the light weight of the dressing, the immediate relief from pain which it affords, and, most important, it permits the joint-functions, motion and weight-bearing, without injury. As a rule the paients may use the limb in any way not causing pain. The time required for complete recovery varies from one to three weeks. The firm, even pressure of the plaster diminishes the lumen of the engorged vessels, thus relieving congestion, relieves the tension on the overstretched ligaments and capsule, thus relieving pain, and hastening the process of absorption.

Plague at Singapore.—An interesting light has been thrown on the vagaries of the plague as regards its transmission by sea, by a detailed report of the cases that have occurred at Singapore by M. F. Simon (*Lancet*, Jan. 20, 1900). The geographical position of Singapore, between India and the West, on one side, and China and the far East on the other, has given the place the position which it holds as a very large center of trade, and renders it especially exposed to danger of plague when that disease is prevalent in the countries from which so much trade and so many immigrants come, and yet very few cases of plague have occurred, none seem to have spread the infection, and many "doubtful cases" seem to have recovered before the disease reached its height. We are led to conclude from the care with which the report has been prepared, and the logical and careful treatment of all doubtful problems, that the plague is not readily transmissible by sea to countries near the equator. It seems to be true in many cases that when an infected patient leaves the country in which the plague is endemic and travels towards the central tropical zone the disease has a tendency to abort. The bacilli seem to disappear, or become modified or inert, leaving the patient to gradually lose the fever and to recover from the glandular affection. The facts bear out the statement that the plague does not spread on shipboard when the patients are removed from endemic environment; and we are encouraged to believe that the danger of conveyance of infection by cargo and baggage for any distance by sea is practically nil.

Etiology of Rectal Stricture.—Acquired strictures of the rectum are much more common in women than in men. Reuben Peterson (*Jour. Am. Med. Assoc.*, Feb. 3, 1900) discusses the etiology of rectal strictures in women under two heads: (1) Those in whom the caliber of the rectum is diminished by pressure from without, organic changes in the walls being secondary; (2) those in whom the rectal walls are primarily affected, the organic changes causing a diminution of the lumen of the rectum. In the cases of the first division the pressure from without is due to a tumor in the pelvic basin, or it may be to a pelvic abscess, or more often to suppurative disease of the appendages. A case is cited in detail illustrating a stricture due to pressure from the latter cause. Under 2 are those cases in which the stricture is due to an inflammatory process in the walls of the rectum itself. An inflammatory process with an increase of connective tissue may lead to contraction and stricture of the rectum. The causes of this inflammatory process, and, therefore, of the stricture, the writer says, may be trauma, dysentery, gonorrhea, tuberculosis, or syphilis. Any trauma to the mucous membrane of the rectum, causing loss of substance and ulceration can result in a stricture. Unskilful operations on the rectum or any resection of the rectum is apt to be followed by stricture. It has been thought that in dysentery, marked by ulcerative processes in the rectum, a stricture might result from contraction following the invasion of the submucosa and muscularis by the ulcerative process. This is probably a very uncommon sequence of dysentery, although a number of cases have been reported. Gonorrhea of the rectum occurs, but while it may cause rectal stricture, it is still far from being proved. Tubercular ulceration and stricture of the rectum have been observed, but more especially as following dysen-

teric ulceration. A careful examination as to the existence of tuberculosis as a causative factor should be made in each case. There is no doubt that syphilis exists in a large proportion of those who have rectal stricture, but whether it is an active or frequent cause of stricture, and if so, in what manner it brings about the condition of rectal stenosis, are questions about which there is a great diversity of opinion. Some observers think that syphilitic strictures follow the breaking down of gummatous deposits in the rectal wall. Others, among whom the writer seems to be, think that the condition is due to the inflammation caused by chancres but not to the chancres themselves. Peterson cites a case in which, although there was no history nor evidences of syphilis, the microscopical findings in nine inches of the rectum removed by operation would lead one to think that such was the cause. Gross examination of the segment removed showed a normal mucosa, which proved that the disease began in and was confined to the deeper layers and hence could not have been caused by chancroid, gonorrhea, or trauma. On the whole the etiology of rectal stricture does not seem to be well established in the greater number of cases. Numerous citations from different investigators appear throughout this paper, and a full bibliography on the subject is given.

Uterine Fibroid.—F. H. Champneys (*Lancet*, Jan. 20, 1900), basing his statements chiefly on the records of five London hospitals, says that the mortality after operation for fibroids is 17 per cent., while the mortality of fibroids apart from operation is 3 in over 2,000,000, or a little over .0001 per cent. In the natural course of events, therefore, fibroid tumors do not cause death, and, therefore, it is not necessary to remove them. Whether or not their removal is desirable depends on the merits of each case. Severe recurrent bleedings may render surgical relief necessary. Severe pain also calls for relief. Dangerous pressure symptoms are usually those causing retention of urine, and call for immediate interference. Rapid growth is often an indication for interference especially when accompanied by bleeding. A cystic fibroid grows persistently and should be removed. Malignant degeneration, although often talked of, is very rarely seen. There is a tendency at present to remove fibroids more freely. Operation is unjustifiable unless the fibroid is dangerous to life, or destructive of the patient's comfort and happiness, in which case the dangers of operation should be explained and the patient allowed to choose.

Huntington's Chorea.—Huyghe (*Le Nord Médical*, Jan. 15, 1900) describes minutely a case of this rare nervous disease affecting a man of thirty-nine years. The maternal grandfather, the mother, and an elder brother were affected in the same way at about the same age, while some sisters of younger age were still free from the disease. Beginning with a staggering, somewhat spastic gait, the legs, followed successively by the arms, head, and trunk, became subject to irregular, involuntary incoördinated, and purposeless movements. These became more energetic when attention was directed toward the patient or when voluntary motion was attempted; yet no matter how violent, they were never followed by rigidity or fatigue. They could be suspended momentarily by the will, and in sleep ceased entirely, yet under excitement were very marked. Speech was explosive, somewhat scanning, and there was slight tremor of the face. Sensation was normal, the patellar reflex present, no ankle-clonus, but there was abolition of the corneal and laryngeal reflexes. The intelligence was poorly developed, thought slow, and he had a tendency to a fixed idea, yet was cheerful and sociable. Later on he developed a condition of dementia.

Local Anesthesia.—A. E. Barker (*Lancet*, Jan. 20, 1900) reports fifty-three cases, including radical cure of hernia, resection of intestine, gastro-enterostomy, goiter, wiring of patella, etc., in which local anesthesia by means of 1 to 1000 eucaine B. in normal salt solution was used. For some patients as much as six ounces of this solution were used, with no ill effect. There is no interference with primary union. Children and timid adults are not adapted to its use, for they are frightened by the surgical surroundings. Acutely inflamed areas cannot be rendered entirely anesthetic. Dragging the mesentery causes a sense of pressure or griping.

Syphilis of the Nervous System.—Syphilis is one of the most frequent infectious causes of organic nervous disease. Wm. M. Leszynsky (*Jour. Am. Med Assoc.*, Jan. 27, 1900) says that every morbid condition of the nervous system which may develop in a person is not necessarily due, however, to a syphilis acquired at some more or less remote period. A favorable prognosis does not necessarily follow the discovery that a lesion of the nervous system is of a luetic nature. It has been demonstrated by clinical experience that patients who have undergone a thorough and systematic antisyphilitic treatment in the early stages of the disease are not insured thereby against subsequent syphilitic disease of the nervous system. Thus it seems that there is no remedy which will protect the nervous system against syphilis. When syphilis attacks the nervous system it affects it in several ways. (1) It may produce an endarteritis in the intracranial or spinal arteries, which gradually leads to thrombosis and occlusion of vessels. (2) It may give rise to a gumma or a local or diffuse gummatous exudate, which may gradually press upon, and finally destroy the nerve-cells or conducting fibers. (3) The cell substance may undergo degeneration because of a gradual interference with its nutrition. The first two forms, known as "inflammatory" or "exudative," often occur within the first two to three years, and may occur within a few months, after infection. They are more or less acute. The third form is called "degenerative" and is chronic. The forms of brain syphilis most dan-

gerous to life are: (1) That which attacks the cerebral arteries, producing obliterative endarteritis, and (2) basal-meningitis and meningo-encephalitis extending to the posterior fossa. The symptoms, which result from the destruction of nerve-cells, when they have persisted for months or years in spite of treatment, are those which are not amenable to further treatment of any kind. When a cerebral artery—it is most frequently the middle cerebral or its branches—becomes the seat of thrombosis, the nutrition of an area of the brain is interfered with, and there is a corresponding impairment of its physiologic function. The amount of disturbance depends upon the size of the vessel involved and of the area supplied by it, and upon whether the occlusion is partial or complete. The cutting off of the blood supply of an area causes a necrotic softening which no antisyphilitic treatment can remedy. Cerebral hemorrhage causing destruction in the internal capsule may be due to the rupture of a syphilitic artery, but antisyphilitic remedies cannot repair the damage. In such conditions it is not only useless, but harmful, to persist in giving mercury or potassium iodide. It is in recent luetic inflammations that antisyphilitic remedies are of value. The rapidity of relief depends on the virulence of the disease, the character and duration of the symptoms, and upon the susceptibility of the patient to mercury and iodine.

Phthisis and Obesity.—Under this title B. Martin (*Le Nord Médical*, Jan. 15, 1900) directs attention to the victims of tuberculosis whose pulmonary lesions are grave and extensive and who yet remain stout and in good condition. Many of these owe their general health to the influence which an arthritic constitution exercises on the progress of pulmonary tuberculosis. Some have presented in youth the stigmata of scrofula; and there is no doubt that the scrofulous diathesis plays some part in the production of these types. Others owe their robust condition to good digestion, rest, fresh air and methodical and intelligent superalimentation. In all, even with cavities, the prognosis is not unfavorable for a prolonged course to their disease, and comparative freedom from disagreeable symptoms. They retain a stout, hearty appearance, eat and sleep well, have neither diarrhea, fever, nor night-sweats, are able to attend to business, and yet have the most extensive lesions in their lungs.

Tensile Strength of Sciatic.—Since the operation of stretching the sciatic nerve has been so frequently performed to relieve intractable sciatica, it is important and interesting to know how much strain upon the nerve is safe and advisable. W. E. Lower (*N. Y. Med. Jour.*, Feb. 3, 1900) has tested the strength of the sciatic nerves of nine subjects shortly after death in a manner similar to that used in the operation of nerve-stretching. In one case the nerve gave way when only one hundred pounds had been used. The average weight required was one hundred and forty pounds. In most of the cases the nerve did not break, but its connections with the cord and membranes were detached.

Home Treatment of Consumption.—In probably 95 per cent. of all cases of consumption a change of climate, or life in a sanatorium, is impossible and they are confined to their homes for treatment. Wm. Osler (*Maryland Med. Jour.*, Jan., 1900) says that the arrest, or cure, of tuberculosis is a question of nutrition entirely, and that the essential factor is to improve the resisting forces of the body so that the disease cannot make further progress, or is eradicated. Fresh air and good food are the most important means by which the nutrition may be increased. While the quality of the air in our cities may not be of the best, it is a great deal better than the atmosphere of the ill-ventilated and overheated rooms in which a great number of phthisical cases live. The writer gives the following directions to his patients: In winter the patient is to be out-of-doors during all of the hours of sunshine except the first two in the morning and the last one at night. If out-of-door life is impossible, the patient should be in a room with southern exposure, with windows wide open, and the bed in the sunshine. If there is a balcony with southern exposure, the patient, well wrapped up, should sit or recline there on a comfortable lounge all day long, except when the weather is very rainy or stormy. The bedroom should be well ventilated at night and the patient gradually accustomed to have the window open. This contiuous open-air life, at rest, has a wonderful influence over the fever of consumption. Often for a month, or perhaps two, or even three months, the temperature will be normal. Those patients do best who are able to take plenty of food. Lack of appetite and weak digestion are due in great part to the fever, therefore, as the temperature falls, the appetite often increases. Each patient should eat as much as he can, even to overfeeding, or stuffing, if possible. Besides the ordinary meals, Osler urges his patients to take raw eggs, beginning with one three times a day, and increasing one a week until they take perhaps 20 to 24 daily. This he finds the most satisfactory and simple diet for the hyperalimentation. The egg, broken into a cup and seasoned with salt and pepper, can be swallowed without breaking the yolk. The main diet should consist of milk, cream, butter, eggs, meat and oysters. Osler divides the medicinal treatment into (1) the use of stomachics, bitter tonics and digestives; (2) cod-liver oil, hypophosphites and creosote for general nutrition, and (3) remedies for cough, pain, night sweats, etc.

Progressive Muscular Atrophy.—Placzek reports an anomalous case of this disease (*Virchow's Archiv.*, 158, p. 105), which, while from a clinical point of view was a most typical case of progressive muscular atrophy and showed the typical alterations in the ganglion cells of the anterior horns of the spinal cord, yet also showed the classical objective changes found in tabes dorsalis. These findings existed without the patient

having shown any of the symptoms of this disease. He had been a type specimen for class demonstration for some time and notwithstanding the most minute examinations had never evidenced any changes in the pupils, nor variations in the sensations of taste, pain, place and had never had any pain nor interference with the functions of the bladder nor of the large intestine. Loss of knee-jerk had developed late in the disease.

Night-Air of New England in Consumption.—C. S. Millet (*Maryland Med. Jour.*, Jan., 1900) tells of the treatment he has instituted and the results obtained in some cases of phthisis which he cites. The treatment consisted in the patient sleeping out-of-doors, except on those nights when it was very rainy. The cot was placed on the roof of a veranda, or on a platform built against the house. The patients used as much bedclothing as was necessary to keep them comfortable. The first case was a young man with a remarkable family history of phthisis. He had incipient phthisis and had lost twenty pounds in weight. For five months he slept out-of-doors every night. At the end of one month his temperature was normal and his cough and dyspnea nearly gone. At the end of five months it was found that he had gained twenty-two pounds. The only medicine he took was some tincture of nux vomica. He worked all during the five months in a factory, and is now perfectly well. A second case was of a man sixty-four years old with distinct physical signs. He has slept out several months, with an improvement in the physical signs and a gain of eleven pounds as a result so far. A third case was of a boy infected with tuberculosis from his father's cow, whose cream he had taken to excess for some time. When the cow was killed the source of the infection was learned. This boy's lungs were so extensively involved that a permanent arrest of the condition is not expected, but after sleeping out-of-doors for six months he gained nineteen and a half pounds and feels so well that he has to be restrained by putting him to bed whenever his temperature goes above 99.5° F. Case four is of a man who has had a pulmonary hemorrhage, and lost a good deal in weight. He had a cough, much weakness, and a small solidified area, so that he stopped work. He had been shut up in-doors eighteen out of the twenty-four hour for a long time. He has slept out-of-doors, gained twelve pounds, and the physical signs have nearly disappeared. Case five is of a young man with marked physical signs. He has commenced to gain in weight, although he has not been sleeping out-of-doors very long. In all these cases the more air they got, the more appetite and the less cough they had. Not a dose of cough medicine was given to any of these cases. Two neurasthenics, one of whom had been condemned to die of tuberculosis, tried sleeping out-of-doors and have been decidedly benefited. The diet was not restricted, but the patients were recommended to take plenty of milk, eggs and vegetables. The patients were required to take a cold sponge bath each morning and another at night, at about 90° F. Millet thinks a patient should rest in bed enough during the day to keep his temperature below 99.5° F.

Formulæ for Bronchitis.—Landesmann states the following formulæ to be in use in Neusser's clinic in Vienna:

1. Expectorant mixture:

℞ Rad. senegæ .....5iiss v
Ac. hydrochlorici dil.....gtt. v
Syr. senegæ .....5iv.
M. Sig. One tablespoonful every three hours.

2. In case of constant, irritating cough:

℞ Peronini .....gr. iii
Aq. laurocerasi .....5ss.
M. Sig. Ten drops three times a day.

3. In case of dry cough:

℞ Tinct. opii .....gtt. x
Decoct. altheæ 5iiss
Syr. rubi id. .....5iiss.
M. Sig. One teablespoonful every two hours, or:

℞ Apomorphin. hydrochlor. .....gr. ½
Morphin. hydrochlor. .....gr. ⅓
Ac. hydrochlorici dil.....gtt. v
Syr. cort. aurant. 5ss
M. Sig. To be taken in one day.

Care of the Mouth in a Healthy Child.—For the first six weeks the infant's mouth should be washed before nursing and also after nursing, unless asleep, with a soft, small square of linen dipped in water. No square should be used more than twice, or at another nursing. By the time the child is three or four months old it will suffice to wash the mouth twice a day. During dentition, however, it should frequently be washed out with cold water. As long as the child subsists on milk and broths the teeth need cleansing with a bit of wet linen only; when solid food is taken a soft, fine tooth-brush should be used. The following makes a suitable powder:

℞ Pulv. oss. Sepiæ 5v
Magnesii carb. 5v
Pulv. rad. iridis flor.....5ss
Ol. menth. piper. .....gtt. iii.
M. Sig. Tooth-powder. Rinse the mouth well after using.—*v. Widerhofer.*

For Sciatica.—Prescribe six to eight capsules daily, each containing one and one-half grains of ichthyol, and in addition inunctions with:

℞ Ichthyol 5v
Chloroform 5i
Bals. tranquillans .....5i.
M. Sig. External use.—*J. Crocq.*

For Aphthous Patches in Infants.—

℞ Sod. boratis 5i
Tinct. benzoin. 5i
Syr. rubi. id.....5x.
M. Sig. External use.

The patches should be touched five or six times a day with a bit of cotton saturated with the above.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, FEBRUARY 10, 1900.

DIET IN CONSUMPTION.

A few years ago French clinicians took up the subject of feeding, overfeeding in fact, and claimed for it practically specific therapeutic properties in the treatment of consumption. Professor Fuster of Montpellier obtained excellent results in a number of cases by the addition to the ordinary diet of raw meat and alcohol. By the administration of from 100 to 300 grams (3 to 10 ounces) of raw meat-pulp and 100 grams (3 ounces) of cognac, he obtained such rapid and marked improvement in his first series of cases that for a time it seemed as though he had found a specific for tuberculosis.

Like so many other vaunted specifics, however, it proved a disappointment. It was demonstrated, however, that in certain cases of incipient tuberculosis, especially where patients have always been free meat-eaters and their appetite and consequently their consumption of meat have decreased, this method of treatment constitutes one of the best therapeutic measures at our command.

Later Professors Debove and Dujardin Beaumetz at the University of Paris recommended forced feeding. In cases in which the patient showed repugnance to taking much more than the usual quantities of food they suggested the use of the stomach-tube, so as not to excite the patient's aversion to the food during its deglutition, as this would be apt to interfere with its digestion. Debove considered that after a period of preliminary training as much as 500 grams (over 15 ounces) of specially prepared meat-powder might be given. This is the equivalent of about four pounds of fresh meat. Besides this, however, the gave from 200 to 400 grams (6 to 12 ounces) of powdered beans or lentils, from 8 to 10 eggs, and advised very free consumption of milk. His patients increased very rapidly in weight under this regimen, as much as twenty to forty pounds in three months, and the ordinary symptoms of tuberculosis of the lungs, the fever, the night-sweats, the coughing, and the expectoration, all improved. A far smaller number of patients than might be imagined were found, at least in hospital practise, to be incapable of assimilating these heroic quantities. Relapses, however, were rather frequent, showing that the gain in strength was not a stable one. It became evident that a more gradual putting on of weight was more effectual in preventing further progress of the disease and avoidance of relapses.

The work thus overdone has not, however, been without is effect on the modern therapeusis of consumption. It has taught a lesson that has been cherished, especially at the sanatoria. Liberal diet to tempt the appetite, tonics to whet it, and the physician's prescription as to definite amounts to be taken, constitute one of the most important legs of the therapeutic tripod, fresh air, abundant food and regular life, upon which the modern successful treatment of consumption in sanatoria rests.

SARANAC HOME FOR ADVANCED CONSUMPTIVES.

An appeal to the charity of the generous that deserves a most hearty and ready response is made in the fifteenth annual report of the Adirondack Cottage Sanitarium. Dr. Trudeau asks for the establishment in Saranac Lake village of a reception-hospital for cases of consumption that are too far advanced for admission to the Sanitarium. He says:

"During the entire year, but especially during the summer months, scores of invalids in the last stages of the disease come to Saranac Lake village, either with scanty purses or wholly without

funds, full of the new hope which the prospect of admission to the institution has brought them only to meet the bitter disappointment of finding they cannot be taken in because their cases are beyond the reach of treatment. Too sick often to care for themselves, without money and without friends, their position is most pitiable and they seek here, often in vain, a place to await the inevitable end. A separate hospital building that would afford a shelter to these stranded and helpless human beings would, indeed, be a fitting complement to the work of restoration attempted at the Sanitarium."

A noble opportunity is thus presented for most helpful beneficence. The great good that has been accomplished at Saranac in the past, under the unselfish care and constant self-sacrificing devotion of its modest director, is too well known to need to be dwelt on here. To Dr. Trudeau, above all others, is due the present practical movement for the care of the tuberculous in this country which promises to be of far-reaching effect in our struggle with the great white plague. The present report of the Saranac Lake Sanitarium furnishes additional proof of the great work that he is doing. The concluding words of the President's report to the Board of Directors are worthy of note:

"Two hundred and fifty-four patients have been treated. To two hundred and eight of these the institution has furnished the best possible means of restoration to health at less than one-half the cost these could be procured for elsewhere, and to forty-six entirely free of cost to them."

We sincerely hope, then, that Dr. Trudeau's appeal will meet with the immediate generous response it deserves, and that this new feature of his work may soon be ready for the poor sufferers, whose needs are so great. We know of no charity where funds could be spent with more actual benefit to suffering humanity than in the way suggested. Physicians who are consulted by the generously charitable for direction in the disposition of funds should bear in mind the modest appeal of the pioneer sanitarium at Saranac.

FRESH AIR AND THE DEATH-RATE OF THE PLAGUE.

In view of the possibility that the plague may become a well-known disease in Europe and America before many years have passed, some figures published by Weir, one of the officers of the Sanitary Service of Bombay, are full of interest. He hit upon the idea that the mortality was greater among patients who live on the ground floor of houses than among those who live in higher stories. By tabulating cases according to the story in which they occurred he found a striking decrease in the death-rate with each additional flight of stairs. Thus the mortality among patients living on the ground floor was 84.7 per cent. For each successive story the mortality was as follows: First, 75.5 per cent.; second, 67.3 per cent.; third, 59.7 per cent.; fourth, 58.1 per cent.; fifth, 45.4 per cent. Buildings in Bombay are not so constructed as to permit an investigator to extend his observations above the fifth story. Proceeding, however, along the same line, the mortality in the tenth story would be 22.7 per cent.; in the fifteenth, 11.4 per cent., and in the twentieth story, 5.7 per cent. Who will dare to guess the amount of rent which the owner of the tallest building will receive for his top story, if the plague reaches Chicago!

In the densest portion of Bombay the houses are built on narrow streets and are surrounded by broad, low verandas, which permit scarcely any air or light to penetrate into the lower stories of the central part of buildings. This decreased mortality for the residents of upper stories held good not only in such houses, but also in better built ones. Moreover, people living in separate houses, as in the country districts, recover from the plague in a far greater proportion than those living in close quarters. The Indian government is considering the advisability of tearing down and rebuilding the houses in the worst district of Bombay, so that the tenants shall have a reasonable amount of light and air. If the new buildings are to be put on a paying basis, however, the rent necessarily charged will be entirely beyond the reach of the inhabitants of the present structures which they aim to replace.

In this connection may also be mentioned the plan proposed by Pierre Apery of Constantinople to rid an infected ship of rats. It is a well-known fact that rats are capable of spreading the plague; hence to fumigate a ship and leave a horde of rats in its hold is a comparatively useless procedure. Apery's plan is to tow the ship a mile or more from land. Cheese and fragments of food are scattered in the most accessible portion of the hold in order to bring together all the rats. A generator of carbonic acid gas is then set to work to form enough gas to displace the air in the lower portion of the ship. Owing to the weight of this gas it sinks slowly to the bottom and gradually displaces all the air. As

a mixture of one part carbonic acid gas and two parts of air is sufficient to suffocate an animal it will not be long before the diffusion of the gas will kill all the rats. As the gas has no unpleasant odor or taste animals are not frightened by it and even if a few should jump overboard the distance from land is so great that they will be drowned. The upper level of the gas may be determined by lowering a lighted candle into the hold. When the gas is reached the candle will be extinguished. When the rats have been killed the carbonic acid gas may be pumped out of the ship. The bodies of the vermin are then collected, disinfected, and destroyed. This method of procedure is simple, easily carried out, and inexpensive in comparison with the effects it accomplishes.

ECHOES AND NEWS.

NEW YORK.

State Medical Society.—Dr. A. M. Phelps of New York, at the recent meeting held in Albany, was elected president of the Society for the ensuing year.

Measles at Fort Slocum.—Measles have broken out at Fort Slocum, on David's Island, where fifteen hundred recruits and nearly a hundred United States Army officers are awaiting transportation to the Philippine Islands. There are now ten cases.

A Correction.—By some inexplicable inadvertence Dr. H. C. Coe in our last issue was designated as Professor of Gynecology at the Cornell University Medical School. This is an error. Dr. Coe is Professor of Gynecology at the Bellevue Hospital and University Medical School. In the last paragraph of his article the word "fortunate" should read "unfortunate."

Shake-up of Pension Surgeons.—The Boards of Pension Surgeons of this city have been reorganized under orders from Washington. The number of boards have been reduced from six to four and fifteen of the former surgeons have been dropped from the Government employ. The three members of the old boards who were retained are Drs. D. D. Stevens, R. T. Bangs and Frank H. Zitz.

Contagious Diseases.—For the week ending February 3, 1900, there were reported: Measles, 817 cases and 21 deaths; diphtheria, 322 cases and 55 deaths; laryngeal diphtheria (croup), 13 cases and 8 deaths; scarlet fever, 220 cases and 21 deaths; smallpox, 2 cases; chicken-pox, 43 cases; tuberculosis, 237 cases and 144 deaths; typhoid fever, 20 cases and 13 deaths; cerebro-spinal meningitis, 3 deaths.

Skin and Cancer Hospital.—Dr. Bulkley will close his course of lectures on diseases of the skin, at this institution, with three lectures on syphilis, February 14th, 21st and 28th, at 4.15 o'clock. The lectures will cover the entire subject and will be freely illustrated by cases, models and plates. These lectures, as in the series just closed, will be free to members of the profession on presentation of their professional cards.

Officers of Obstetric Section.—At the January meeting of the Section on Obstetrics and Gynecology of the Academy of Medicine, J. Riddle Goffe was elected chairman and George Gray Ward, Jr., No. 230 West 59th street, secretary. Dr. Samuel Hall, one of the three surviving founders of the Academy was present and gave some interesting reminiscences of practise in New York fifty years ago.

Sales of Antitoxin—A bill has been introduced in the Legislature in reference to the sale of lymph and antitoxin in Greater New York, which provides that in case the amount of lymph or virus shall exceed the amount required in the proper performance of its duties, the Board of Health may cause such excess to be sold at public auction, but the aggregate net amount of such sales shall not in any one year exceed $5000. It has been the practise of the Board to sell its excess of antitoxin at private sale.

Arrest of Fifteen Midwives.—Dr. Feeney of the Board of Health applied, on February 4th, for warrants for fifteen midwives who, he declared, were conducting lying-in institutions on the East side without permits from the Health Department. Dr. Feeney declared that the number of midwives had increased recently and that they were conducting a business prohibited by the Sanitary Code. They failed generally to make any report to the Board of Health of the infants born on their premises. A police sergeant and a dozen policemen were on hand and made affidavits on which the complaints were based.

The Removal of Dr. Backus.—Governor Roosevelt has failed to reappoint Dr. Truman J. Backus manager of the Long Island State Hospital. This failure is in effect a removal of Dr Backus. The latter has filled his position most capably. A few weeks ago the Governor distinctly gave those interested to understand that he recognized the necessity of reappointing Dr. Backus and should send in his nomination shortly after New Year's. Instead, he has sent in the name of another man. The real explanation may lie in the fact that, as the chief member of the Board of the Hospital, Dr. Backus some time ago, for the very best reasons, it is said, compelled the resignation of the hospital's superintendent, who was the son-in-law of Senator Raines.

Mount Sinai Hospital.—The plans for the new buildings of the Mount Sinai Hospital are being completed rapidly by Architect Arnold W. Brunner. Most of the money has been raised, and the remainder, it is expected, will be obtained without difficulty. The excavations will begin early in the summer. The total cost will be considerably more than $1,000,000.

The new hospital will occupy a group of buildings of marble and light brick, with marble trimmings, covering the block bounded by Fifth and Madison avenues and One Hundredth and One Hundred and First streets. All the buildings will be connected by covered corridors. The roofs of the ward buildings will be used as roof gardens, and will have sun-rooms in the central portion for use in the winter. All will be strictly fire-proof and finished as far as possible in the interior with tile and marble. The advance in the price of building material will necessitate an additional expense of $50,000 in construction and there is some talk of delaying the erection of the building on this account.

Mortality in New York State.—The State Board of Health at Albany reported on February 2nd that the number of deaths from all causes for 1899 was 121,820. This is 850 more than in 1898 and 4740 more than in 1897, which was a year of unusually low mortality. The death-rate per 1000 is 17.3, which is the average death-rate for the past ten years. The infant mortality was less than the average by nearly 5000 and is 1800 less than that of last year, 29 per cent. of the deaths occurring under five years of age against the average of 35. A point to be noted in connection with the antitoxin treatment is that compared with the average of ten years the deaths from diphtheria are but little more than half as many, although the number is 175 greater than in 1898. Diarrheal diseases caused 2000 fewer deaths than the average. Whooping-cough, measles, scarlet fever and malarial diseases all caused fewer deaths than the average. Smallpox caused 21 deaths, all save three of which occurred in New York City. The outbreak in the western part of the State, beginning in May, 1898, continued till midsummer of 1899, reaching forty-five localities in fourteen counties and attacking 320 individuals and produced but one death. At the end of the year the State is believed to be free from smallpox. Grip is estimated to have caused 7000 deaths from January to April. An epidemic of modest severity prevailed at the close of the year. The deaths from acute respiratory diseases were excessive on account of it, nearly 18,000 deaths, or nearly 15 per cent. of all deaths, having been caused by such diseases.

PHILADELPHIA.

Medico-Legal Society.—This Society has elected as officers for the ensuing year: President, Dr. Albert M. Eaton; first vice-president, Dr. L. H. Adler, Jr.; second vice-president, Dr. Samuel Wolfe; secretary, Dr. Clewell; treasurer, Dr. G. W. D. Peltz; librarian, Dr. J. D. Nash.

Health Report.—The number of deaths for the week ending February 3rd was 507, an increase of 9 over the previous week and a decrease of 5 from the corresponding week last year. Contagious diseases: Diphtheria, 128 cases, 24 deaths; scarlet fever, 66 cases, 5 deaths; enteric fever, 39 cases, 4 deaths.

Dr. S. Weir Mitchell's New Story.—Dr. Mitchell's new novel, "Dr. North and His Friends," will begin its career as a serial in the March *Century*. It is said to present under the cloak of fiction many of the actual scientific observations and phenomena that have come to the doctor during his long career as physician and man of letters.

Heating of Street Cars.—The recent cold weather has brought this question again to the front. The Traction Company officials state that they are willing to please the people, but there is such a diversity of opinion they do not know what is wanted. Physicians are of various opinions. The chief surgeon of the Department of Public Safety believes the cars should not be heated, except those making long runs, and those only on exceptionally cold days, such as this city seldom sees.

The Widal Test.—Dr. A. V. Meigs does not place any value on the Widal test in the diagnosis of typhoid fever. An expert at a distance with only a drop of the patient's blood cannot tell much about the diagnosis. Again, the test gives a positive reaction in blood from patients suffering from tuberculosis and other diseases as well as typhoid fever. In a recent case the City Hall laboratory reported a positive reaction and the hospital laboratory a negative one with blood from the same patient. Dr. Meigs believes the test will pass out of use in a few years.

Pure Food.—An eminent lecturer has claimed that the Dairy and Food Division of the Department of Agriculture of Pennsylvania has done more for the health of the citizens during the four years of its existence than have all the doctors in the State. This rather minimizes the importance of the disciples of Esculapius, but there is some truth in the statement, as the percentage of adulterated foodstuffs has been reduced from 90 per cent. to 10 per cent. The Commissioner contemplates investigating the liquor supply, which is also included in the law. That field is a vast one.

Pennsylvania Hospital.—Dr. J. M. Da Costa exhibited a case, February 3rd, which necessitated a differential diagnosis between tubercular meningitis, with arrest of the process and recovery of the patient, and non-tubercular meningitis in the presence of tuberculosis of the lungs. The patient was a colored man who had a typical attack of basilar meningitis with a right-sided hemiplegia. He has practically recovered from the meningitis. At the same time he has lung symptoms and tubercle bacilli are found in the sputum. Notwithstanding this fact, Dr. Da Costa believes it to have been a case of non-tubercular meningitis for the following reasons: First, the presence of marked head symptoms—retraction, rigidity, tenderness in the back of the neck; second, there were none of the secondary phenomena common to tubercular meningitis, such as crying, screaming, spasmodic contractions, etc.; third, the fact that the patient has recovered.

A remarkable pathological specimen was also shown. This was the large white kidney of chronic parenchymatous nephritis. The interesting point was that the patient had had but one kidney, the left one being congenitally absent. The right one had hypertrophied to probably twice the normal size to meet the demand for double work. When this immense organ became diseased it showed the pathological changes in a most striking manner.

Medical Standard.—The Association of College Presidents of Pennsylvania, at a meeting held in Harrisburg, January 12th, adopted the following resolution: "*Resolved*, that the Medical Council of the State of Pennsylvania be requested so to construe the state law and their own decisions that graduates of reputable colleges be eligible for examination by the Council after three years of study in a medical college, provided that work practically equivalent to the first year of our best medical colleges be done in the undergraduate course." The Association is in sympathy with efforts made to raise the standard of medical practitioners, but believes that the admission of college graduates to the second year of the medical course is not detrimental to a high standard.

One of the most zealous champions of the college graduate is Dr. W. W. Keen, who asserts his belief that "a college graduate who has pursued absolutely no medical studies during his college course would at the end of three years in a medical school be better fitted, on the whole to practise medicine than would a man who had gone through the entire course of four years of the medical school without such previous training. But when the college student comes to us with a certain fixed number of hours of study of anatomy, embryology, bacteriology, chemistry, etc., then it is preeminently true that such a man, even although he studies only three years in the medical school, will be a more accomplished physician than the other."

Academy of Surgery.—At a meeting held February 5th Dr. John B. Deaver reported a case of pancreatic cyst. The patient was a woman of 58 years of age, who, although the condition was one of twelve years' standing, had good general health, eating and sleeping well. The distention of the abdomen, however, had caused a prolapse of the vagina some two years ago. The abdomen measured 52 inches in circumference at the level of the umbilicus, the liver and heart being slightly displaced upward. Diagnosis was difficult, but palpation detected a plate of cartilage which led to the diagnosis of a cyst. The abdomen was opened and found to contain large quantities of an oily fluid. The presence of a pancreatic cyst, adherent to the parietal peritoneum, was also revealed. The free fluid was evacuated and the geography of the cyst and its adhesions obtained. The abdominal wound was then closed and an incision made directly into the cyst. Its contents were evacuated, the cavity drained, and the patient made a perfect recovery.

Dr. Thomas K. Morton exhibited a boy from whom he had removed the astragalus for clubfoot ten years ago. The foot is almost as perfect as a normal one, no ankylosis having taken place. Dr. Morton has removed the astragalus in about 100 cases. He has never found it necessary to tie a vessel, suppuration has never taken place, and ankylosis has not occurred in a single instance. The wound is closed without drainage and the leg put on a right-angled tin splint.

CHICAGO.

Evanston Hospital.—A ward for contagious diseases is to be erected in connection with the Evanston Hospital. The wing will be two stories and basement, of pressed brick and stone, connected with the main building by an open corridor. The cost of the improvement is estimated at $20,000.

Vital Statistics.—According to a tabulated statement in the weekly bulletin of the Health Department, there were 45 fewer deaths during the week ending January 27th than the week preceding, and 96 fewer than for the corresponding period of 1899. The reduction is chiefly in the chronic diseases and among the aged. The death-rate a year ago was excessive, owing to the fatalities from influenza and its complications. **Deaths** from scarlet fever and diphtheria show a substantial reduction. The rate for typhoid is the lowest for this season for years. Medical inspectors of schools for the week examined 7376 pupils, of whom 452 were excluded from the schools.

Physicians' Club of Chicago.—At a meeting held January 29th, medical legislation was the subject for discussion. Hon. S. P. Shope, ex-Justice of the Supreme Court, discussed in a masterly manner the constitutional aspects of medical legislation. Dr. J. W. Pettit of Ottawa, Ill., analyzed the present state medical law, pointing out its points of strength and weakness. Dr. George H. Simmons, editor of the *Journal of the American Medical Association*, followed with remarks on the need of organization and cooperation to promote proper medical legislation. A general discussion followed which was participated in by Drs. I. N. Love, Weller Van Hook, C. B. Johnson, James A. Egan, Harold N. Moyer, Clarke W. Hawley, and Frances Dickinson. A resolution was offered and adopted urging Governor Tanner to appoint Dr. George W. Webster as a member of the State Board of Health to fill the present vacancy.

The Schoenborn-Beele Splint.—Dr. Edward H. Lee advocates the use of this splint and says that among its many advantages which it offers are that it can be applied immediately; it is light and neat; there is no necessity of padding with cotton; it is not apt to produce decubitus; it may be removed and put back in place in a very short time,

and the cost of the material is moderate. He knows of no other splint that will adapt itself so perfectly to the form of the limb as this one. In 1891, during his term of service as intern under Professor Schoenborn at the Julius Hospital in Wurzburg, Germany, he had the opportunity of becoming familiar with the making and application of this splint. For the past seven years he has used it in the Cook County Hospital, the Alexian Brothers' Hospital, and in private practise in a great number of cases. It has also been used extensively by a number of the interns of the Cook County Hospital and by some of the members of the attending staff, and the results have been excellent.

Heart's Ease and Mind-Cure.—The Rev. P. S. Henson of this city recently preached a sermon on this subject, and among other things he said: "By mind-cure I do not have reference to bodily cures wrought by mental processes. There is a great truth that lies in that direction and mental therapeutics are forging more and more to the front in the practise of the best physicians, while innumerable money-making fakirs are availing themselves of it for the working of what are accounted by their credulous dupes as miraculous cures. And presently these humbugging hypnotists are riding in chariots, with liveries and servants in attendance on their highnesses, and are organizing banks and projecting ideal cities on a scale of imperial splendor, toward whose erection their confiding followers are expected to contribute all their hard-earned savings, while the projectors, with plethoric pocketbooks, flit across the sea in search of health or pleasure. This is mind-cure that is akin to madness. And Christian Science, which of late has had such a sweep of power, appeals to the same principle, and works by the same principles, and makes big money for its shrewd discoverer. What religion there is in it is a flat denial of the fundamental truths of the gospel."

Tuberculin a Failure in Diagnosis.—At a recent meeting of the stockraisers and dairymen, held in this city, a special committee, after stating that it has never been proved that tuberculosis is transmissible between cattle and human beings, summed up the objections to the use of tuberculin as follows: "The temperature of healthy animals and those affected with the disease sometimes rises after the injection of tuberculin. Some tuberculous animals do not react to tuberculin. Tuberculin does not determine the stage of the disease, but condemns animals which might live for years and possibly recover. Tuberculin may produce the disease in healthy animals, and certainly hastens its progress in those affected. It has been proven that identically the same action as that of the tuberculin can be produced by the injection of the extracts of other products of various bacteria, even such as are known to have disease-producing properties. Tuberculin is a poison, and it is not desirable to inject it into the blood of a cow that is giving milk for the use of the public. Tuberculin develops the germ that it was intended to destroy, adding poison to poison, and being cumulative in its effects. The cases in which it has apparently caused no harm to healthy cattle are so scarce and irregular that no general conclusion can be drawn from them. The expert skill with which the process has been employed at the experiment stations cannot be applied in the general use of the test. The disease can be stamped out in any herd of cattle without the tuberculin test. The compulsory slaughter of cattle under the tuberculin test has been compelled and abandoned wherever it has been tried to any great extent. This is noticeably true in the States of New York and Massachusetts, where laws similar to those now in force in Illinois were repealed as a nuisance. The whole scheme is a vain attempt to eradicate a disease by removing the natural results of unsanitary conditions, while leaving the proximate cause, proper conditions for the promulgation of germs, to go on unmolested. The last germ cannot be destroyed without altering the entire plan of the Creator. What is needed is a law to compel conditions for the prevention rather than means for the extermination of the disease, when that extermination calls for the extermination of cattle." The report concluded that the quarantine cuts off the supply of fresh and healthy cattle, and that the State Live Stock Board is wrong in regarding tuberculosis as a "dangerously contagious or infectious disease," justifying the destruction of private property without compensation.

Prevention of Tuberculosis.—Dr. Charles J. Whalen of the Chicago Medical Society said the number of deaths from tubeculosis in Chicago for the year 1898 was 2416, and the average reported deaths from this disease annually for the past ten years was 2378, 11 per cent. of the mortality from all causes. The United States Government spends annually millions of dollars to prevent the spread of cholera, yellow fever and smallpox, yet to the presence of tuberculosis there exists a spirit of apathy that is a reproach to our intelligence. Intestinal tuberculosis is extremely rare. While infection from milk may be possible, it is extremely infrequent; the chief means of communicating the disease in childhood is by direct infection by inspired air.

The best means of prevention is the destruction of the sputum and the removal of those affected, who are too poor to receive the necessary care at home, to an isolation hospital, which should be provided by the State. It would not be judicious at the present time to make the registration of this disease compulsory, for inspection and disinfection can safely be carried out without working such a severe hardship to these unfortunates. Too rigorous or inhuman restrictions might undo the work already done, or bring it into disrepute, consequently only such precautions should be taken as are really necessary.

It is gratifying to know that Illinois is taking advanced ground on this subject. This view has

also been gaining in favor of late in other States as well as abroad. France and Belgium and other foreign countries have provided sanatoria for the treatment of tubercular children. They are also provided with a school, so that the children not only have a chance to be cured, but at the same time receive an education. The poor adult consumptive, too, needs the protection and care of the State, and every municipality should have a sanatorium where those dependants who are afflicted with the disease may receive the necessary attention. The establishment of isolation hospitals for the consumptive poor is the best step that can be taken for the prevention of the disease. Isolation hosptials are not to be advised for the well-to-do, who can afford and will carry out the necessary instructions at home, for it must be admitted that the presence of so many invalids in all stages of the disease must have a depressing influence. A good trained nurse and control of the patient at home will be found more efficacious and satisfactory to the patient than isolation at a sanatorium.

GENERAL.

The Influenza Reaches Spain.—It is reported from Madrid that there are 5000 cases of influenza in that city. Terrible snow storms prevailed last week throughout Spain and Portugal.

Sunstrokes at Buenos Ayres.—One hundred and two sunstrokes were officially reported in the city of Buenos Ayres on February 3rd. Of these 93 were fatal. The temperature was 120 in the shade.

Faith Curists Arrested.—On complaint of the health office at Lincoln, Neb., warrants have been sworn out for the arrest of four Christian Scientists who were responsible for the death of the child of one of them. The complaint charges violation of the Lincoln health laws.

Epidemics and Prayer.—Influenza is epidemic in Italy and Spain, and the Pope has ordered special prayers to be offered up for the cessation of the affliction. There are 30,000 cases in Italy, but the majority of them are of a mild character. In Barcelona, Spain, there were 124 deaths from the disease on January 26th.

Rat War in Denmark.—Both city and country houses in Denmark are so infested by rats that a society has been organized under the name of the National Danish Rat-Exterminating Society. The record of one week's work announces the death of 90,000 rats. A crematory is being planned for the purpose of disposing of their carcasses.

The Bacillus of Pink-Eye.—Much interest is excited by the announcement that the bacteriologists of the Liverpool School of Tropical Diseases have discovered the bacillus of "pink-eye," the well-known equine epidemic. This has usually been regarded as influenza of the horse and a comparison of the new bacillus with the alleged germs of human influenza will be awaited with interest.

Havana's Vital Statistics.—A report on the vital statistics of Havana for the year 1899, compiled by Major Davis, chief sanitary officer, shows 8153 deaths from all causes in an estimated population of 220,000. Of these deaths 1163 were from enteritis and 1307 from tuberculosis. There were but 103 deaths from yellow fever. Eleven deaths were due to leprosy. The number of contagious and infectious diseases reported was 6442, of which 284 were yellow fever. There were recorded during the year 4181 births, of which 1516 were illegitimate.

Women Physicians.—Two women physicians of California have been placed in official positions within a week. One is Dr. Beatrice M. Hinkle, who was appointed Assistant City Physician by the Board of Health of San Francisco, and the other is Dr. Agnes Walker, appointed from Washington as Quarantine Inspector and Federal Quarantine Officer at Kinyoun. She is the first woman on this coast to receive a Federal appointment to office. Her duties will be to examine women and children who arrive on vessels from infected ports and care for them in quarantine.

Sir Richard Thorne's Successor.—The President of the Local Government Board, the chief sanitary authority of England, has appointed Mr. Wm. Henry Power, assistant medical officer, to the position of chief medical officer and inspector to the Board, left vacant by the death of the late Sir Richard Thorne-Thorne. Mr. Power is well and favorably known in the profession apart from his public sanitary work and the appointment is regarded as a well-merited honor. Dr. H. Franklin Parsons, President of the Epidemiological Society, succeeds to Mr. Power's post, and Dr. R. Bruce Low fills the gap made by this promotion.

The Explosive Lyddite.—The London *Graphic* says: "This high explosive, thus called from the name of the small Kentish town and gunnery center where the experiments with it were made, is nothing else than picric acid brought into a dense state by fusion. Picric acid is a bright yellow substance freely used in peaceful industries for dyeing purposes. It is obtained by the action of nitric acid on phenol or carbolic acid. It burns very violently, and, owing to the tremendous blast produced by the explosion, the destructive effect of a bursting shell filled with it is some eleven times greater than that of a shell filled with powder. Common shells of forged steel filled with lyddite are used with 6 and 9.2-inch breech-loading guns, and with howitzers; also with 4 to 6-inch quick-firing guns."

An Appendicitis Club.—An appendicitis club was formed in Cleveland, O., about February 1st. It is proposed to make this organization a national one, and to establish branches in all the cities of the United States. To become a member one must have been operated on for appendicitis.

There are two or more grades. The ordinary members are those who have been operated upon but once. The higher ranks are composed of those who have submitted to two or more operations. Honors will increase according to the number of operations undergone. No doubt those members will label themselves after the manner of the man who became unconscious in an accident. There was found upon his chest, when the clothing had been removed from it, the legend: "My appendix has been removed."

Medical Control of Marriages.—A bill has been prepared in Colorado which, if passed, will place the granting of marriage licenses in that State in the hands of a board of medical examiners. In each county there is to be a board, to consist of three physicians, no two of the same school; and where possible the board is to have one or more female members. Licenses are to be granted to men not less than twenty-five years old and to women not less than twenty-two. To secure licenses men and women must be free from dipsomania, insanity, tuberculosis, hereditary asthma, scrofula, epilepsy and other diseases. There must be no blood relation between parties who wish to contract. No certificate entitling one to receive a license shall be granted to a person notorious for moral depravity or to one who shall at the time of the application be on trial, under bonds, or in prison for felony.

The Hospital Ship "Maine."—A dispatch has been received from Lady Randolph Churchill, who is on board the American hospital ship "Maine," at Durban, saying the vessel will be stationed there for the present. The "Maine" was filling with wounded men, including members from the battle of Spion Kop. The members of the Maine Committee in London are more active than ever, and are determined to make this American charity a success and keep it going until the war is finished. Mrs. Adair, who is now head of the committee, is perhaps the most prominent and influential American living in England. She is a daughter of General Wadsworth, who was killed at the battle of the Wilderness, and is the owner of the largest cattle ranch in the Panhandle of Texas. The energy and ability with which she manages this big property she is now devoting to the "Maine." Mrs. Chamberlain, the Duchess of Marlborough, and others who hitherto have taken no active part in the work, are now much interested and are determined to raise the £3000 monthly which is necessary to keep the ship going.

The Plague.—The epidemic continues its ravages in India, where the condition is aggravated by the famine. The mortality in Bombay February 7th was unprecedented in the history of that city, the total number of deaths reaching the extraordinary number of 408. A rather sensational report comes from London to the effect that the plague exists in England in an unsuspected form. At Southampton during the last few months dogs have been attacked by a disease which is highly specific in its nature and is gradually spreading to other parts of the country. The fatality among dogs is great. Although the disease has not been diagnosticated as bubonic plague the opinion is that it has been brought on ships by rats and so communicated to the dogs. At Lisbon a decree has been issued announcing that the bubonic plague has disappeared from Oporto and that the quarantine of that port has been raised. The sanitary and hygienic measures instituted at Honolulu have been successful in staying the progress of the disease, but the condition has not yet reached a stage in which it can be pronounced free from danger.

Obituary.—Sir Thomas Grainger Stewart, the noted Scotch physician, died in Edinburgh, February 3, 1900, aged sixty-three. Dr. Stewart was born in Edinburgh on September 23, 1837. He was educated at the High School and University of Edinburgh, and after graduating studied in the universities and hospitals of Berlin, Prague and Vienna. On his return to Edinburgh he became resident physician in the Royal Infirmary. In 1876 he was appointed professor of practise of physics at the University of Eninburgh. He was the author of "Bright's Disease of the Kidneys," which has passed through two editions in Great Britain and two in America. He was a member of many learned societies, an honorary fellow of the Royal College of Physicians of Ireland, and of the College of Physicians, Philadelphia, an M.D. of the Royal University, and received the like honor from the University of Dublin. He was president of the British Medical Association in 1898. In 1882 he was appointed Physician in Ordinary to Her Majesty the Queen in Scotland. He received the honor of knighthood in 1894. He was representative of England at the International Congress on Tuberculosis which met at Berlin in May of last year.

Women Nurses in the Army.—A bill providing for the employment of graduated women nurses in the hospital service of the United States Army has been introduced in both houses of Congress. The bill provides "that women nurses in the proportion of not more than 10 per cent. of the sick and wounded in general and post hospitals of fifty beds and upward, shall be employed by and constitute the women's nursing service of the medical department of the Army. That there shall be a superintendent of women nurses, who shall be a woman graduated from a general hospital training school for nurses. That the nurses shall be graduates of general hospital training schools having courses of instruction lasting not less than two years; that they shall be appointed by the Surgeon-General under regulations approved by the Secretary of War; that they shall receive $40 a month when on duty within the limits of the United States, and $50 a month when on duty outside of the limits of the United States." The bill provides further that nothing in its terms shall be construed to limit the power of the Secretary of War in time of war or national

disaster to avail himself of duly qualified Red Cross nurses or nurses of other worthy societies or associations.

Indiscriminate Charity.—Mr. Andrew Carnegie in an after-dinner speech at the Lotus Club recently vigorously denounced the custom of indiscriminate charity. He said: "Let a multi-millionaire take his millions to the slums and call the people together, saying 'There is a wrong distribution of wealth in the world. You have not got your share. I give to each one of you his share of my millions.' Let that be done in the morning, and let the millionaire return at night to see what good his action has done, and he will find not happiness, but pandemonium. Let him distribute another million and another million every day for a month, and pauperism will increase every day. At the end of the month, seeing the result, he will wish that he could crawl and ask pardon for the harm he has done. He has done more injury in a month than he will do good in all the rest of his life. He has taught the hitherto self-respecting working family that industry leading to self-support and independence has no reward beyond almstaking, idleness and debauchery. It was this class of charities and the sums rich men give to applicants and to societies in order to be relieved of the trouble of investigation, of which I ventured to say that of every $1000 so bestowed $900 had better be thrown into the sea."

Anopheles and Malaria.—The work of narrowing down the causation or conveyance of malaria to this genus alone of all the mosquitoes and gnats is steadily progressing. Major Nichols of the Army Medical Corps reported some time ago the discovery in Burmah, which appeared to him identical with the descriptions published of Anopheles. Its habits were identical, its larvæ found in similar pools, and all the barracks near these puddles were extremely malarious. Specimens were sent to Major Ross, who identified them at once as belonging to the genus and probably to a particular species, *A. Rossii*. So that now in Italy, in West Africa, in India and in Burmah, this single genus has been closely associated with malarial conveyance, if not actually identified as the sole carrier. The task of exterminating malaria appears to be narrowing itself down most hopefully to the destruction of this particular group. As it is few in numbers and both fastidious and readily accessible as to its breeding-puddles, the project is far from Utopian, although it seems almost too good to be true. In this connection it is amusing and irritating, as the *Times* says, to note that Dr. Robert Koch uses the words "my theory" when he comments on new evidence from Java supporting the view that there is a close, and perhaps direct, relation between malaria and mosquitoes. Dr. Koch is undoubtedly a very great bacteriologist, and the world is indebted to him for much good work done and several important discoveries made; but he was not the first to suspect the mosquito of infecting unhappy humanity with the germs of malaria, and the theory that they do so is his only in the sense that he gave it comparatively early adhesion. Dr. Koch has been charged before with endeavoring to monopolize credit belonging to other men, and here seems to be a clear case against him.

Medical War-News.—The South African war continues to be emphatically a surgeon's war. The deaths to date stand, killed in battle, 858; died of disease, 238; a proportion which almost reverses the ordinary ratio usually reckoned at about two deaths by disease to one by bullets in campaigns which are at all prolonged. No doubt the disease will gain in relative importance as a factor in the mortality as the war proceeds, but so far the fever and dysentery death-rate has been an extremely low one. The only exception is Ladysmith, where, under the trying conditions of the siege, the fever-mortality has steadily risen until a recent report from Sir George White, covering only five days, gave a list of 28 deaths due to typhoid and dysentery as against 6 due to wounds. The death-rate among the wounded appears to be rising slightly, apparently on account of the larger proportion of other than Mauser bullets used by the Boers or, perhaps, to the "nicking" of these merciful missiles to increase their stopping power. The rate is still, however, below six per cent. A surprising feature is the small percentage of wounds inflicted by shells, a mere handful when compared with the thousands of bullet-wounds.

One of the most astonishing features of the war is the way in which money continues to pour in to supplement the deficiencies of a dilatory and undeserving Government. Whole companies and regiments are being raised and equipped at private or municipal expense and now one of these, the Imperial Yeomanry, is to have a special hospital of its own provided by private munificence. It is to be a base-hospital near Cape Town, to contain 520 beds, and be known by the name of the corps, although, of course, open to the sick and wounded of all arms of the service. Nearly two-thirds of the necessary funds have been already subscribed and the site is being selected for the building.

The military inactivity of the last few weeks has left the Medical Corps chiefly concerned with the task of nursing and sending home the wounded and counting up the results. But this has kept them busy enough, Magersfontein, Tugela, Colenso, sent flood after flood of wounded into the field-hospitals, tasking the resources of the service to the utmost. They proved equal to the strain, however, and the papers are full of praises of the efficiency and success of *our* department of the campaign, some frankly alleging that it is the only one thus far which reflects much credit upon its organizers. No less than 800 wounded were poured into the field-operating tents the day of the Tugela reverse alone, but every one of these was carefully and thoroughly dressed on the

field, often under fire, brought into shelter before sunset and safely landed at one of the line-hospitals within forty-eight hours. To dress, and remove from the field of battle, 800 wounded men within four hours of the cessation of firing is, we think, something like a record performance in ambulance and bearer work. The hospital trains seem to have proved remarkably efficient, being brought right up to the field of battle, equipped with every comfort and even luxury, iced soda-water, champagne, soup, etc. As each train carried from one hundred to a hundred and twenty patients, the transference of even such large numbers as the Tugela casualties to the line-and-base-hospitals can be rapidly carried out.

CORRESPONDENCE.

A PECULIAR PHENOMENON OF SIGHT.

To the Editor of the Medical News:

Dear Sir:—I have recently observed quite a peculiar phenomenon in connection with the perception of moving objects. Thus far I have failed to find its explanation in the teachings of medical optics. The experiment to demonstrate this is briefly as follows: Look steadily at a large wheel revolving just fast enough for the spokes not to be seen. Now, if the eyes are closed as in the ordinary act of nictation, at the instant of closure *the spokes of the wheel appear perfectly visible*, as though the wheel had suddeny stopped. If the eyes are voluntarily closed slowly this will not occur. An easy way to observe it is to notice a carriage wheel in which the observer is riding. It is best seen if the spokes are black and the light is diminished, as after sunset.

Getting no explanation from the profession or optical works, I wish to refer the matter to you and your publication for some elucidation. It seems to me to be due to some internal ocular change due to the instantaneous compression of the eye in nictation, and the short duration of this changed vision views it as still.

J. D. Poe, M.D.

Dallas, Texas, December 22, 1899.

[Dr. Ward S. Holder of New York to whom this question was submitted, offers the following explanation: The phenomenon described is somewhat analogous to the more familiar one observed where a wheel rotating in the dark is illumined for an instant with the electric spark. The illuminated wheel makes a single impression upon the retina and, therefore, appears to be at rest.

The impression upon the retina produced by the spoke of a rotating wheel persists for a certain time, and if successive spokes make their impressions upon the retina before the preceding impressions have faded entirely away the result is a faint continuous retinal impression, and the individual spokes are not perceived. But if this continuous impression is interrupted suddenly by winking the eyes or, better, by passing a screen quickly between the eyes and the wheel, it is apparent that the next succeeding retinal impression (provided the rotation is not too rapid) will be of the individual spokes and thus for an instant the rotation will seem to have ceased.—Ed.]

SEROTHERAPY AND GOAT'S MILK.

To the Editor of the Medical News:

Dear Sir: The following communication received by me from a physician in Arizona is interesting and instructive. It contains valuable reference to climatology, serotherapy and dietetics, which I have thought would prove of interest to the readers of the Medical News:

"Globe, Arizona, ——.

"My Dear Doctor: In the *Journal of the American Medical Association*, of January 14, 1899, I noticed an article on 'Serum Therapy in Tuberculosis which was of especial interest to me. Two years ago, while practising medicine in St. Louis, Mo., I was suddenly taken with a hemorrhage from the lungs; the next day I made an examination of the sputum and found bacilli. The hemorrhage was as much a surprise to me as were the bacilli, as I did not notice anything unusual in my condition until the hemorrhage, then cough, sweats and fever began, with a repetition of the hemorrhage a month later. At that time Koch's tuberculin R. was given to the public and Dr. Carl Fisch of St. Louis, who is a personal friend of mine, was experimenting with this remedy according to Koch, and he and Dr. E. W. Saunders advised me to try it. This I did, taking the injection every day. The night sweats and fever disappeared, and the cough was slight. It has, however, always been a question to my mind whether tuberculin R. was the cause of my improvement. After taking the injection for eight weeks (at this time I was living in the country and not practising) I left for Arizona. I had been in the Gila valley about three weeks when I had another hemorrhage. This lasted a few days and disappeared entirely and was not attended with fever or night sweats. About five months later, February, 1898, I went to Phoenix to take the medical examination to practise. While there I had another hemorrhage, but paid little attention to it. Again fever and sweats did not follow. The hemorrhage usually occurred on retiring at night and on arising in the morning. Eight months later I wrote to Dr. Fisch, telling him of my condition and he sent me more serum. I began to use it and in two weeks I had another hemorrhage, which lasted about three weeks, bleeding every morning and night regularly and a few times during the day. These hemorrhages were more severe than usual. I was very much reduced physically by them and I took a vacation and went to Guadalapara, Mexico. Here the winter was not as severe. The dyspnea which followed the last hemorrhage disappeared, but the cough and expectoration were

quite profuse. In the latter part of March I had another hemorrhage, which lasted about six days. I was then in Aqua Caliente, Mexico, in the hospitals of the Mexican Central Railroad, as assistant. Fearing the confinement and filth of Mexican cities, I returned to Arizona, and have felt much better since my return. The peculiar features are the absence of sweats and fever. The hemorrhages return every six months, but they do not confine me to bed or hinder me in my work. Was the severe hemorrhage in October due to the T. R.? I stopped using it when the hemorrhage began. *The cause of my resisting the disease, I feel, lies in my good appetite and out-of-door life, and Arizona is the ideal place.* As to goat's milk, last week while making a call in the country I stopped at a goat-ranch, and the goatman offered me some milk. I had never tasted goat's milk before; *it was just grand,* much better than cow's milk, and thus when I came across the article quoted I was quite interested.

"It is held that infants are immunized against the ordinary contagious diseases by the antitoxines in the mother's milk! We know that in Russia they use Kumiss, or fermented mare's milk for the treatment of tuberculosis. In the July number of the *Wide-Wide World Magazine* is a most interesting article by Victor Pitnethley, entitled "The Kumiss Cure." This is all about a wonderful 'farm' in the Russian steppes where consumptive people are made well by drinking mare's milk and basking in the glorious sunshine. Both normal horse blood serum and mare's milk, as well as normal goat blood serum and goat's milk, I have argued contain natural antitoxins and are powerful agents to bring about a 'cure' in tuberculous patients. I have seen Dr. Fisch inoculate two guinea-pigs with diphtheria toxin. One of these pigs he gave goat's milk and it lived; to the other he gave no goat's milk and it died. The same result I have seen with tuberculin R. in monkeys. I am interested because I am in such a condition, again interested as a physician. I believe as you do, that the secret of success lies in pure air, sunshine and good digestion. If there is anything I can assist you in, as to information about Arizona or Mexico, I am at your service, or should you have any suggestion or care to offer any information as to goat's milk, etc., kindly mention it.

"I am, yours fraternally,
"A. F. Maisch, M.D."

This report is very interesting to me because as early as 1867 I was stationed at Fort Cummings, New Mexico, the "Sentinel of the Southwest," as it was then called. From Fort Craig, after crossing the river, beyond the dreary Jornado del Muerto, or Valley of Death, or literally translated, Journey of Death; at the southernmost end, after a march of ninety miles or more, was Fort Selden. Then sixty-five miles of desert to Fort Cummings and forty-four miles further on southwesterly, Fort Bayard, which has been opened recently as a consumptives' hospital. (See Medical News, December 23, 1899). No location could be better, for north, south, east and west the climate is superbly suited for the treatment of tuberculosis. I have been stationed at Fort Elliot, in Texas, and at Fort Union, New Mexico, and know the Santa Fé trail from beginning to end and believe in New Mexico for the cure of tuberculosis. Beyond Fort Bayard the trail goes westward into Arizona, and all through the region the atmosphere and the climate generally is life-giving in the highest degree.

In 1895 I visited and reported on the climatology of southeastern New Mexico. The present year I had introduced, through my friend and Congressman, General Cogswell of Massachusetts, a bill to create a sanatorium for consumptives at some abandoned military post in New Mexico, but although much time and money was freely spent to carry on the good work it met with obstacle after obstacle. The Army Medical Department has at last successfully inaugurated this noble undertaking, but I understand that no provision has been made for citizens to enjoy its privileges. The history of this effort will be found in the *Journal of the American Medical Association,* 1896, and Medical News, December 23, 1899. The Marine Hospital Service has also received, within the year, through President McKinley, the use of another military station for the same beneficent purposes. I am thoroughly in accord with Dr. Maisch in what he has said of the life-giving atmosphere of that remarkable "health section," and it seems to me that this would be a most excellent opportunity for some competent persons, with medical assistance, to engage in goat-farming in New Mexico, and to make provision for the suitable care of tuberculous patients in connection with the ranch. Patients could secure the benefit of the climate, of the goat-milk treatment, and of the normal goat serum treatment, all at the same place.

W. K. Parker, M.D.,
Formerly A. A. Surgeon, U. S. A.

Westboro, Mass., December 13, 1899.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, January 27, 1900.

THE GREAT LONDON HOSPITALS AND THE WOUNDED —THE YEOMANRY HOSPITAL—INOCULATIONS FOR TYPHOID—"ANTIS" TO THE FRONT—A MEDICAL PARLIAMENTARY CONTEST—DECLINE OF THE INFLUENZA—THE ROYAL COMMISSION UPON THE WATER SUPPLY AT LONDON.

An illustration of how this war is shaking London to its very center has been furnished this week by the response of the London hospitals to the Government circular asking what number of beds they could devote to the care of the wounded from South Africa. Guy's, Westminster, Charing

Cross and the Royal Free have each promised twenty beds, St. Bartholomew's fifty, and the Brompton Hospital for Consumptives will also do its share. It is intimated that St. Thomas's, University College, the London and the Great Northern will also devote a certain number of beds within a few days. In spite, however, of the prompt and generous response of the hospitals, this action of the War Office is of decidedly doubtful wisdom and is exciting much criticism. First, because a London hospital is a chronically overcrowded institution, so that whatever beds are allotted to soldiers are taken from the poor, whose only resource in case of illness is the hospital. Second, because a city hospital-ward, although an unspeakable boon to the city slum-dweller and an immense improvement upon his ordinary quarters and surroundings, is far from an ideal health resort. To deliberately send patients from the open air of the veldt and the sea into the fog of London for their health is little short of absurd. In fact, the whole performance smacks of lack of judgment and initiative on the part of the authorities, especially in view of the scores of generous offers of beds in sanatoria and country-houses already made. A single well-built shed hospital in a bracing country neighborhood would accommodate as many patients as the scattered and hardly-spared beds of all the London hospitals put together and under much more ideal conditions for recovery. Several of the hospital boards, while patriotically offering the beds requested, have quietly but firmly remonstrated with the War Office for demanding such a sacrifice from the poor.

The Yeomanry Hospital scheme grows apace. Mr. Alfred Fripp has been appointed senior civil surgeon and Dr. Washbourn senior civil physician and a staff of twenty other civilian medical men is to be attached. Her Majesty has testified her cordial approval of the undertaking by the donation of $500 for the equipment of two beds. And Our Surgical Highness Lister has on behalf of the Jenner Institute presented the hospital with a supply of typhoid antitoxin.

Now that the death-roll at Ladysmith from enteric fever is steadily recording from three to ten names per day, a keen, practical interest is being aroused in the question of "vaccination" for typhoid. This procedure was initiated by Professor Wright of Netley Army Medical College, some three years ago, but until within the past twelve months had not been carried out upon a sufficiently extensive scale to enable any decision to be arrived at upon its efficacy. It has, however, been urged with much confidence upon the troops sent out to South Africa by the Army medical officers and a considerable majority of them are reported to have submitted to it. Hitherto almost the only reports of positive results from the vaccinations had been those of the eight subalterns in the Khartoum campaign, six of whom submitted to inoculation, while two preferred to take their chances without. Not one of the six inoculated contracted the disease, while both the others fell ill and one of them died. The other instance was that of the Kent County Asylum where during a severe epidemic of typhoid eighty-four of the attendants and staff were inoculated. Of these not one contracted the disease, while of their fellows who declined vaccination sixteen developed typhoid.

So that Professor Wright's preliminary note in the current *British Medical Journal* upon the inoculations made by him last year upon the English troops in India is peculiarly timely. Although the period elapsed is far too short for positive conclusions to be drawn yet, the results seem really significant already. A reduction of the disease-rate among the 2835 inoculated to 0.95 per cent., as compared with a rate of 2.5 per cent. among the 8460 non-inoculated under observation in the same regiments, can hardly be a mere coincidence. Especially when the death-rate in the same groups for the period is 0.2 per cent. and 0.35 per cent., respectively, a reduction of nearly 40 per cent. If this rate of difference be constant, it could amount to the prevention of 1000 cases of typhoid and 200 deaths per annum in the British Army in India alone, where typhoid is peculiarly rife and responsible for 37 per cent. of the army death-rate. Certainly the inoculations upon the embarking volunteers will be carried out with even greater hopefulness and rigor in the light of these results.

Of course the vivisection and vaccination shriekers could not miss some opportunity of bringing themselves into notice through the war excitement. One of them is fiercely protesting against "poisoning" our brave fellows and numbing their intellects by injections of "decaying animal tissues," by which they elegantly refer to the typhoid vaccine. The other has lifted up its voice loud and long against the rejection of volunteers for active service on the ground of non-vaccination, which it describes as "sacrificing the interests of the Empire in support of a hotly disputed medical dogma."

The resignation by Sir John Lubbock, on his elevation to the peerage, of his seat in Parliament has given rise to a contest of singular interest to medical men. The two most prominent candidates for the vacant seat are both members of the profession, in a broad sense, Sir Michael Foster, the famous physiologist, and Dr. W. J. Collins, the late chairman of the London County Council. As the former represents the Conservatives and the latter the Liberals, the profession seems safe to be represented in the House of Commons for this borough whichever way the election goes. The seat in question is that of the University of London and the voters are the alumni of the University resident in England, wherever scattered. Fancy having Harvard represented in Congress! A slight ripple has been stirred up in medical circles by a letter in one of the journals signed "M.D.," accusing Dr. Collins of being an anti-vaccinist and urging the medical alumni of the University not to vote for him. There appears to be reason for suspecting the strict orthodoxy

of the candidate in this respect, but we fear appeals of this sort will bring him more votes than they will cost him.

The great epidemic of influenza of the past month seems to have at last reached and passed its climax. Its death-roll last week reached only 208 names as compared with 340 and 316 the two previous weeks. The deaths from diseases of the respiratory organs also fell synchronously from 1222 and 994 to 728, which is only 41 above the corrected (10 years) average for this week of the years, so that, although the death-list is still far too high, we may hope that the worst is over. A similar decline is registered in the other large English towns, especially in the south. The rate of Brighton, which, two weeks ago stood at more than double its ordinary level (44.9 per 1000), has now fallen almost to the normal, while in the midland towns the decline is much less and in the northern Sutherland and Newcastle the rate is still increasing. Which seems to support the belief that the epidemic is sweeping over the country from south to north. Several towns, notably Brighton and Plymouth, have registered the highest recorded death-rate in their municipal history during this epidemic. In one feature it has singularly resembled our own great outburst in 1890 in the large proportion of the deaths which occurred in elderly and particularly in aged people. While we have this favorable news to give of the decline of the epidemic in Great Britain, the spread of the disease continues on the Continent. The mortality at Munich has been greatly increased thereby.

The Royal Commission upon the Water Supply of London, after sitting nearly three years, during which time two of its members have died, has at last been delivered of its report. It is unanimously in favor of the purchase of the undertakings and plant of all the Metropolitan Water Companies by the municipal authorities and their consolidation and management under a special Water Board of not less than thirty members. So far its decision is excellent, but when the report goes on to recommend purchase at practically the Companies' own valuations and declines to recommend any restrictions upon the taking of flood-water from the Thames, we fear few municipal reformers and sanitarians will agree with it. It also dismisses the superb scheme of the London County Council for bringing a really adequate supply of water from the Welsh mountains, as a project with "something attractive" about it but as quite unnecessary for practical consideration at present, inasmuch as the Thames will furnish an abundant supply until at least 1941! This is extraordinary, to say the least of it, for even supposing this sublime confidence in Father Thames to be not misplaced, when even now every droughty summer arouses serious misgivings, the date fixed is only forty years distant now and it would take at least ten or fifteen years to bring the Welsh water into London. Moreover, what as to 1942 and after?

A NEW INSTRUMENT FOR MEASURING BLOOD PRESSURE—PARTIAL GANGRENE OF PUERPERAL UTERUS—MODERN VIEWS OF OPERATION FOR CANCER OF THE STOMACH—TRACHOMA—INTERMITTENT GOITER.

AT the Berlin Medical Society, December 13th, KAPSAMER spoke of the new instrument for measuring the blood pressure which is called, after its inventor, Gäntner's tonometer. The instrument consists of a pneumatic ring, connected through an air-tight T-shaped tube, with a mercury manometer on one side and a rubber bulb on the other. The pneumatic ring is pushed over the second phalanx of a finger, care being taken to avoid the joints. The distal portion of the finger is then made anemic by an elastic finger-cot on an elastic ring. By compressing the rubber bulb a few times the pressure of air in the apparatus is increased until it is sufficient to control the flow of blood through the finger. The finger-cot is then removed and the air in the tube is gradually allowed to escape until the pressure in the ring becomes so feeble that the finger-tip begins to redden. At that moment the pressure as indicated by the monometer is read. The blood pressure drops 10-40 mm. of mercury when a patient is anesthetized to return to normal after anesthesia. Great hemorrhage or the evacuation of large quantities of pleuritic or peritonitic fluid will cause a sudden drop in the pressure. Vomiting, the ligation of a large artery, such as the femoral, or the application of an Esmarch's bandage will cause a rise in blood pressure. In explanation of these and other instances of alterations in the blood pressure, Kapsamer says that the pressure in the blood-vessels is due to three factors: (1) The energy of the heart; (2) the resistance of the walls of the vessels, and (3) the volume of the blood. The fall of pressure during anesthesia is due to the lessened vascular resistance, since the pulse-rate remains about the same. The same is true of the fall in pressure which follows the evacuation of large quantities of fluid from the pleural or peritoneal cavity or of gas from meteoric intestines. The normal pressure is from 100 to 130 mm. of mercury. It is important to determine how low the pressure may go and life not be lost. A man with a recurrent sarcoma of the pelvis had repeatedly a pressure of 70 mm. Another with recurrent carcinoma of the leg had for some months previous to his death a blood pressure of 65 mm. After an exploratory laparotomy, a man having a large cystic tumor, was found to have a blood pressure of 60 mm. The same evening the pressure was 55 mm., but the patient apparently felt well. At midnight he was dead. An unusually large goiter was removed from a woman aged fifty-nine years. The blood pressure after the operation was 75 mm. Six days later it had fallen to 50 mm. In ten hours she was dead. A woman aged fifty-two years jumped from the second

story. She was unconscious for a few minutes, and then came to herself; except for a few bruises she seemed perfectly well. Her pulse was normal. The blood pressure was tested and found to be only 40 mm. In thirteen hours she was dead. From these cases it appears probable that the lowest pressure compatible with life is about 60 mm.

FRAENKEL having used the tonometer for several weeks testified to its reliability. It has its limitations, however. In aortic insufficiency, for example, this instrument records a greater increase of tension than really exists. This is because it records the maximum pressure, and in the diseased condition the tension in systole is far above normal. It sinks very much in diastole, but that is not indicated by the tonometer. A second shortcoming of the instrument is the fact that it records the pressure in a small peripheral artery. Such a vessel is far more subject to contraction of its muscular walls under psychical influences than is a larger vessel. Hence it is desirable to make two separate tests to determine the blood pressure. In chronic nephritis and arteriosclerosis the pressure sometimes rises to 220 mm. The instrument will sometimes show increased pressure under circumstances which would cause it to pass unnoticed should the physician merely feel the pulse. On the other hand, in the aged, whose arterial walls are rigid, the physician's finger may tell him of high tension when in reality the pressure is far below normal.

At the session of December 20th, GOTTSCHALK showed a part of the wall of a puerperal uterus which had undergone gangrene and had been cast out through the vagina on the 18th day after labor. The woman was a primipara with a contracted pelvis. After three days of labor the head was not engaged. Version was performed and a living child extracted. The mother was much exhausted. Next day she had a chill and a temperature of 105° F. On the fourth day, the high fever continuing, the uterus was washed out with a one-per-cent. lysol solution, and then with 60 per cent. alcohol. Three days later the condition of the patient was so bad that heart stimulants were given hourly, and 24 ounces of 1 per cent. saline solution were injected subcutaneously. The patient perspired profusely, passed a great quantity of urine for a few days, and after expelling a portion of the uterus measuring 6.5 x 2 x 1 inches she finally recovered. Gottschalk attributed the gangrene to the anemia of the uterus brought about by an almost pulseless condition of the patient for two days before the birth of the child, and aided perhaps by large doses of ergot and the use of an ice-bag. The effect of the alcohol, if such existed, must have been distinctly secondary.

At the Free Union of Surgeons of Berlin, December 12th, LINDNER discussed the advantage of the Kader-Mikulicz method of operating for cancer of the stomach by the removal of lymphatic glands, as well as the tumors in the stomach. Kader admits that this prolonged operation has a higher mortality than simple excision, but he hopes that the ultimate results will be better. These hopes, *a priori*, appear to be not well founded, since merely the glands are removed, while the connecting lymphatics are left. Statistics of twenty-eight cases of recurrence also show that while recurrence was local in fifteen cases and in the neighborhood in twelve cases, it was glandular in only one case. Lindner advocated gastro-enterostomy in severe cases of gastric cancer. During the eight months previous he had performed Wöfler's gastro-enterostomy with anastomosis of the ascending and descending intestinal legs, and had to report only one death after operation and that from cardiac failure.

At the Vienna College of Doctors of Medicine, January 15th, H. ADLER spoke of the newer methods of treatment of trachoma, a disease now generally considered to be of bacterial origin. Prophylaxis is most important. In all institutions affected children should be kept away from those who have none of the symptoms of the disease. The speaker referred in detail to the various methods of treatment by caustics and by instruments. He emphasized the importance of combined instrumental and medical measures, speaking very highly of Knapp's forceps.

At the Imperio-Royal Society, January 12th, HITSCHMANN showed a young man, aged twenty-three years, who suffered from intermittent goiter. Only about twenty such cases have been reported. They are of three classes: Those which have external varicose veins but no exophthalmos; those having visible varicosities with exophthalmos, and those having intermittent exophthalmos without visible symptoms. The case presented was of the second class.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Annual Meeting, Held January 2, 1900.

Facial and Retrobulbar Neuritis.—Dr. William M. Leszynsky presented a woman, thirty-eight years of age, who came to him first on October 11, 1898. At that time there was a complete facial paralysis of the left side, which had existed for five weeks. There was a loss of taste, but the eyes remained normal. The facial paralysis was preceded by severe pain and tinnitus in the left ear, lasting several days. She was treated by galvanism in the usual manner. Two months later, while under treatment, she complained of severe pain in the left supraorbital and left temporal regions, lasting continuously for over a week. She then became totally blind in the left eye. The pupil was absolutely immovable, and the ophthalmoscope showed edema of the papilla, but nothing else. Within a week well-marked papillitis could be detected in the left eye. The vision in the right eye was normal. Under treatment by mercurial inunctions and the

internal use of iodide of potassium vision improved somewhat, and on November 4th, vision in the right was 22/100ths. She now has optic atrophy, and the vision is decreased. The faradic irritability has returned, but is still below the normal. A diagnosis was made of facial neuritis and a retrobulbar neuritis arising from periostitis in the optic canal. This is a very unusual condition, and for this reason the patient was presented. Dr. De Schweinitz of Philadelphia recently reported two or three cases, but in them the retrobulbar paralysis developed nearly a year and a half after the neuritis. The case also shows that a return of faradic irritability does not necessarily mean a return of motility.

Dr. G. M. Hammond asked if uremia could be absolutely excluded in the case just presented.

Dr. Leszynsky replied that there was a complete absence of all urinary signs and symptoms. The neuritis seems to have been either of rheumatic or syphilitic origin. There are some elements in the case that lead him to think it possibly of syphilitic origin.

Syringomyelia.—Dr. Joseph Collins presented a man whom he had been asked to see a few weeks ago by Dr. Powell. The latter had removed a small lipoma from the lumbar region, having no connection with the spinal cord or membranes, contrary to the opinion that had obtained before operation. The patient is thirty-six years old, and contracted syphilis nearly five years ago. Since that time he has been under almost constant treatment. He complained of weakness in the right leg, pain in the back, and slight numbness in the left lower extremity. Careful inquiry elicited the fact that while still a boy he experienced difficulty in keeping the right leg in the stirrup when riding horseback, and noted in that foot what had really been a clonus. The knee-jerk is exaggerated on the right side, and on that side there is also ankle clonus. There is absolute thermo-anesthesia from the fourth intercostal space on the left side down to the tip of the toe. The diagnosis is syringomyelia.

Dr. Richard H. Cunningham said that he remembered having tested the sensation of this patient some time ago, but did not recall the existence of thermo-anesthesia. He looked upon the case as one of tumor of the cord, and not as essentially syphilitic.

Dr. Pearce Bailey said that several similar cases had been met with at the Vanderbilt clinic during the past three or four years. It is the custom there to examine regularly for such anesthesia, and while the individual case could not be recalled, it is exceedingly probable that if thermo-anesthesia had been found it would have been noted and remembered.

Dr. M. Stieglitz was inclined to accept Dr. Collins's view of the pathology, although it is unusual to find such extreme spasticity in such an early stage. He would like to know if there is any muscular atrophy present anywhere in the body, and if there is any change in the sympathetic supply to the eyeball.

Dr. C. L. Dana also looked upon the case as one of syringomyelia. Some of the cases of slowly developing spastic paralysis without sensory symptoms seemed to him to be really examples of early multiple sclerosis. He had seen such cases develop characteristic eye symptoms after a good many years.

Dr. Graeme M. Hammond said he had an opportunity of examining this man, and agrees entirely regarding the clinical symptoms. He accepts the diagnosis given by Dr. Collins. This case is certainly not one of recent development.

Dr. Joseph Collins, in closing, said that the right lower extremity is one inch and a half smaller than the left. There are no ocular symptoms, and no vasomotor disturbances of the face. There might have been in the beginning an area of gliomatosis which, at first, had connected with the central canal.

Tumor of Aqueduct of Sylvius or of Cerebellum.—Dr. Collins presented a boy of eighteen exhibiting all of the cardinal symptoms of tumor of the aqueduct of Sylvius or of the cerebellum. About three years ago it was first noticed that he was lethargic. Fourteen months ago, while climbing into a window, he fell and shortly after this he began to vomit and suffer from periodic headaches. These were followed by increasing sleepiness, and by a disturbance of the gait. His limbs can be thrown around, and the joints bent backward in a remarkable way. The knee-jerks are feeble. There is no nystagmus, and no true cranial nerve palsies or ocular palsies. Both eyes show choked disk and slight pigmentation.

Dr. C. L. Dana thought this peculiar drowsy condition characteristic of tumors in the aqueduct of Sylvius, and extending forward into the third ventricle, yet, in other respects, the symptomatology is that of a cerebellar tumor. If the tumor were in the aqueduct of Sylvius it could not be causing much distention or infiltration, or there would be some eye symptoms. The weight of the evidence seems to favor a tumor in the cerebellum. It is possible that the double-jointed condition was increasd by his present affection.

Hemorrhagic Encephalitis and Myelitis.—Dr. Charles L. Dana and Dr. M. G. Schlapp presented this report, which was read by Dr. Dana. The subject is a man of sixty-seven years of age, who came under observation last June. There is no clear history of intemperance. His previous health has been good. During the last seven years of his life he has been somewhat of an invalid. On June 4, 1899, he complained of headache, and after taking two cups of tea went to bed. He fell out of bed a few hours later, and then discovered a left hemiplegia. He was removed to Bellevue Hospital. At that time his temperature was 104° F., but it quickly fell. On examination, he could not protrude the tongue, which was immobile. He was paralyzed almost completely on the left side. The lips were markedly affected. The abdomen was somewhat rigid. The patellar reflexes were normal, and ankle clonus was absent. Sensation to heat and cold was normal.

The urine showed nothing abnormal. Four days after admission he had a chill and the temperature rose to 105.5° F., and examination of the blood showed the malarial plasmodium. After having been in the hospital for one week it was noted that there was no paralysis of the right arm or leg, and the most notable feature was the paralysis of the tongue and lips. He was unable to make any distinct articulate sounds. He could swallow and cough, and understood perfectly what was said to him. Death occurred on June 25th. At the autopsy, made by Dr. Dana, only the brain and cord were examined. There was slight edema and congestion of the arachnoid. The vessels of the base were not atheromatous. In the right hemisphere was anarea of capillary hemorrhage and softening in the lower portion of the posterior central convolution, and superior part of its marginal gyrus. It involved mainly the deep part of the upper lobe of the fissure of Sylvius. In the centrum ovale were two or three smaller areas of hemorrhage. There was no evidence of hemorrhage or softening in any other part of the cerebrum, cerebellum or pons. The spinal cord showed two foci of softening, one in the upper dorsal and the other in the lower. The brain was hardened in formalin, and then stained by various methods. The microscopical examination showed in the affected area much dilatation of the blood vessels, small extravasations of blood, a great proliferation of cells, showing an irritative reaction to the hemorrhage—in other words, the evidence of an encephalitis, apparently secondary to the disease of the blood-vessels. There were also small areas of softening of the brain in the neighborhood of these hemorrhages, also the result of the breaking and obliteration of the vessels. The walls of the latter were somewhat thickened, but gave no evidence of syphiltic process. Sections and drawings were exhibited. The examination of the rest of the brain failed to show any evidence of sclerosis. The medulla showed no evidence of softening or of inflammation. Examination of the spinal cord has not yet been completed. The cord showed a small center of poliomyelitis in the dorsal region. Below this is a more extensive poliomyelitis, involving both the anterior and posterior horns. The appearances closely resemble those described by other writers on encephalitis hemorrhagica. Regarding the occurrence of speech disturbance in a case of this kind, Dr. Dana said that in the great majority of cases of this form of hemiplegia there is no speech disturbance except a few days after the attack, which might easily be ascribed to shock. In another class of cases of hemiplegia there is a slight uncertainty in speech, lasting for several months. In still another class the hemiplegia is associated with some difficulty of speech, and sometimes with true aphasia. He had never observed any sensory aphasia in these cases. When the lesion is well below the cortex, involving the motor neuraxons and the collaterals going to the opposite hemisphere, there will be some hesitation in speech; when the lesion is still lower down, disturbances of speech are absent. There is a very general opinion prevailing to the effect that bulbar palsies of cerebral origin are due to lesions in the lenticular nucleus, but our present knowledge of the anatomy of the brain makes such a view untenable. Concerning the disturbance of the tongue, the speaker said that Dr. Collins, who has given a critical description of this subject, placed the tongue center in the anterior and upper part of the foot of the anterior central convolution. Some of the centers of the movement of the tongue are probably deep in the fissure of Sylvius, and not subject to experimental stimulation. In the case under discussion it is interesting to note that mastication and deglutition are not impaired. The case also brings up the subject of non-suppurative encephalitis. It seems to be established that there is an infectious hemorrhagic encephalitis in infants; also that there is a hemorrhagic poliomyelitis in adults; also an acute hemorrhagic encephalitis of adults due to some acute infection such as influenza. In the case presented there is a distinct history of malarial infection and of alcoholism, and this combination, it is reasonable to suppose, is responsible for the lesions discovered. Such a case might be classified under the name of degenerative hemorrhagic encephalitis. An examination of the autopsy records of 67 cases of apoplexy showed that 42 of them were hemorrhagic, 11 embolic, and 11 thrombic, and 3 encephalitic.

Dr. E. D. Fisher agreed with the reader of the paper that, in a small percentage of cases, there might be an encephalitis, and that the spinal cord might also be involved. He had seen cases affecting the right hemisphere in which the aphasia was permanent. It is not common, of course, for such persons to lose the memory of names and things, but he can recall a few such cases. He did not believe there are enough fibers passing over from one side to the other to account for that. The right hemisphere is the region in which the center of speech is fixed, and while it is more accentuated on the left, the right cannot be entirely excluded. This belief is based on clinical experience.

Dr. B. Onuf thought that, as a rule, dysarthria rarely occurs in connection with lesions of the internal capsule; it is more often met with in lesions of the cortical foci. It is most frequently observed with lesions of the left hemisphere. To explain this he assumes that all the articulatory muscles are represented in each hemisphere, and that the center of the right hemisphere is subordinated to that of the left hemisphere through the fibers of the corpus callosum. If there is a lesion of the right hemisphere there may be a temporary dysarthria; if, however, there is a lesion of the left hemisphere the dysarthria would be permanent. On the other hand, if the lesion were in the internal capsule, whether on the right or on the left, the dysarthria would occur. If the dysarthria were marked it could be stated almost certainly that the lesion is in or near the cortex. He believes that there is a double speech center, and

that that of the right hemisphere is subordinated to that of the left.

Dr. Fisher asked Dr. Dana whether he had noticed any difference in the character of the articulation in the first few days between a right hemiplegic and a left hemiplegic. Personally, he has found as much difficulty in the one case as in the other.

Dr. Collins thought the paper most interesting because adequately proving that a single lesion is capable of producing diffuse and multiple lesions in the central gray matter. It is the first communication of the kind ever presented in this country. The paper called attention to the possibility of an acute malarial infection giving rise to such a process. The changes discovered in this examination are those which might be expected theoretically. He does not see how this report could have much effect on the question of aphasia because serial sections of the entire length of the medulla oblongata were not presented—indeed, he is doubtful if the patient had true aphasia. There might have been an affection of the central allocation of the tongue not implicating the muscles of the lips and palate, in part due to the very small focus of inflammation in the medulla oblongata. The explanation given by Dr. Onuf was the one that he has himself long held, and which is the same given by Dr. Dana in this report.

Dr. M. G. Schlapp said that the inflammation in the medulla seemed to be a very recent one. There is a small round-cell infiltration, but the large proliferating cells found in the cortex are not present. The infiltrating stage and the proliferating stage are both represented in the cortex.

Dr. Dana, in replying to Dr. Fisher, stated that his experience has been that dysarthria occurred about as often with right hemiplegia as with left, and that dysarthria is practically due to the size of the lesion. If the lesion be very large and the hemiplegia complete there is almost always dysarthria. Where there is only slight hemiplegia associated with dysarthria it is probable that the lesion is high up in the cortex, or involves a part of it. He thinks that this case illustrates dysarthria rather than aphasia. The weight of evidence in this case seems to indicate a paralysis of the tongue is the result of a cortical lesion—a sudden apoplectic lesion. There was no hemorrhagic process in the medulla.

Lead Paralysis with Autopsy.—Dr. B. Onuf reported this case. The patient is a man, thirty-seven years of age, with a good family and personal history. He was a painter for many years, and had one attack of lead-colic some years ago. A short time ago he had a severe fall, and for some days afterward appeared in a dazed state. From March until August he had not painted; then he began painting again with colors containing a large percentage of lead. He kept this up during the month of August, but during this time suffered frequently and severely from colic. At the end of August he became quite ill, and, in three or four days, was almost helpless in the lower extremities and in the left arm. On admission to St. Catherine's Hospital, in September, 1899, there was complete flaccid paralysis of both lower extremities; absence of both knee-jerks; marked tenderness of the nerve-trunks and muscles of the lower limbs. There was also paralysis of the flexor muscles of the left arm and of the extensors of the fingers. The gum showed a "lead line." Under diaphoretic treatment the spontaneous pain ceased. On October 4 he had an attack of severe dyspnea, and on the following morning died in a second and similar attack. The extensors and flexors of the right arm were wasted, as were also the peroneal muscles and the flexors of the thigh. The left lung was the seat of a bronchopneumonia. Microscopical examination showed what appeared to be a poliomyelitis of the anterior horns. The parts examined so far are the second and fifth lumbar, and here and there is an enormous infiltration of the walls of the blood-vessels with round cells. This infiltration of cells is so extensive as to lead to very general distention of the nerve cells. The anterior roots are markedly affected, but the posterior roots of the lumbar are normal. The plantar nerve shows increase of connective tissue and endarteritis obliterans. The liver was examined by Dr. Bookman for lead, but none was found. As five weeks had elapsed such evidence is not of much importance.

Dr. L. Stieglitz said that this case showed in the human being exactly what he found in his case of experimental lead-poisoning. In experiments on 36 animals he obtained in one guinea-pig only an acute poliomyelitis at the post-mortem, and also cell infiltration and more or less destruction of the nerve-cells around the foci. This guinea-pig was acutely paralyzed. Death occurred within twenty-four hours. In his experimental cases he obtained, in every instance, changes in the ganglionic cells themselves. The case presented in the paper is, of course, an atypical one of lead-poisoning, and hence would not justify any conclusions regarding the ordinary pathology of lead-poisoning. The cases reported by Oppenheim and by Herter seem to him the most typical.

Dr. E. D. Fisher thought the clinical history of this case corresponds more with that of alcoholism than of lead-poisoning. As a rule, in cases of lead-poisoning the lower extremities are the parts first involved. He had written on this subject some years ago, and called attention to the occurrence of these degenerative changes in the brain and cord in cases of alcoholism. Apparently the case reported combines both alcoholism and lead-poisoning. The changes in the central nervous system were pretty well established.

Dr. W. M. Leszynsky said that it also seems to him that the reader of the paper has not proved the connection between the lead-poisoning and the post-mortem findings. Certainly the case appeared to be one of alcoholic toxemia, or of some acute infectious process.

Dr. Hammond said that while it is very probable that the man suffered from lead-poisoning, he doubts very much if the lead had anything to

do with the condition of the spinal cord; it is much more probable that it was the result of some acute infectious process. He does not believe that a case of true lead toxemia has been reported in which such changes in the nervous system were observed.

Dr. Cunningham said that some weeks ago he met with a case of lead-palsy in a man who at the same time developed a mild form of influenza. The phenomena observed were quite similar to those reported in the paper.

Dr. Collins also took the ground that in addition to the lead-poisoning there had been an alcoholic neuritis, or some acute infection giving rise to the changes in the spinal cord.

Dr. Onuf said that by reason of the frequent attacks of colic during the last few weeks the man had been unable to work and this seemed to show the close connection between the lead-poisoning and the other symptoms. Cases of alcoholic neuritis usually present quite a different picture from that exhibited by his case. The autopsy revealed evidence of a certain amount of alcoholism, it is true, but the man had not been drinking for a considerable time previously. There was no history of an acute infectious process.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON PEDIATRICS.

Stated Meeting, Held January 11, 1900.

Thomas S. Southworth, M.D., Chairman.

Spina Bifida.—Dr. Sarah Welt Kakels presented a patient with this anomaly. There had been a normal birth and the infancy had been normal. The child does not seem to suffer any pain in the tumor except when it becomes red and inflamed from some external irritation. The coccyx in the case deviates slightly to the left and the cystic tumor of the spinal bifidi is also to the left. Pressure upon the tumor seems to cause no medullary or cerebral symptoms. The tension of the tumor increases when the child cries or coughs. There is a good chance to see this in the case, as the patient is at present suffering from whooping-cough. The tumor is made very prominent on coughing. These tumors are more frequent in females and are usually accompanied by other anomalies. In this case, however, the child seems to be perfectly well except for the presence of the spina bifida itself. Just above the tumor the characteristic dimple of spina bifida can be seen.

Dr. Vanderpoel Adriance presented a macerated specimen of an anencephalous monster. The cerebrum in the case was absent and all the bones covering the side and vertex of the head were absent, or extremely rudimentary. The bones in the upper part of the face were defective in the same way. The cerebellum was practically complete and the bones at the base of the skull were perfectly normal.

Dr. Charles G. Kerley presented a series of light splints which prevent flexion beyond a right angle and so make it impossible for a child to scratch its face, or to rub its nose, or pull its ear, or rub its eyes in any of the irritative affections of these parts. They would also prevent thumb-sucking. Despite the presence of the splint children have so much movement in their shoulder-joint that they are still able to reach the top of their heads, so that in eczema capitis it is necessary to pin the sleeve to the dress in addition to the splint. There was also a splint to prevent masturbation. Extension of it is possible only as far as a right angle or even less. It is intended to be worn only during sleep, or when the child cannot be under observation. Then it serves its purpose very well.

Dr. Herman, said in discussing the subject, that the cases in which such appliances are most needed are among the very poor. For them the expense of a splint is too great. In the European clinics the custom is to put cardboard cuffs on the children that prevent flexion at the wrist, and fasten their arms by a piece of tape or a shoestring that passes around the back. This is very simple and costs practically nothing.

An Epidemic of Measles.—Dr. Vanderpoel Adriance reported the statistics of an epidemic of measles at the New York Nursery and Child's Hospital. While in private practise measles is an extremely simple disease, involving very little mortality, in hospital practise it is the most serious of the children's diseases. Its mortality is apt to be high, it is very contagious and the contagion endures for a long time. The difference between the contagiousness of scarlet fever and measles is well illustrated by the condition of affairs at the hospital during the present summer. One case of scarlet fever developed in the wards and was immediately segregated. Only one other case of the disease developed as the result of the exposure of the children. Measles occurred and in spite of the most careful precautions continued during the whole summer. Altogether 96 cases were treated. It is often said that measles protects very well against second attacks, but that is not the experience at the Nursery and Child's Hospital. In 16 of the 96 cases the attack was the second one. In 14 of these 16 cases the former attack of measles was not assumed to have taken place on the word of the mother, or any imperfect history, but because the patient had been actually under observation at the hospital during the preceding attack. Diphtheria is the most frequent complication. Once diphtheria has gotten into a hospital ward it is extremely difficult to get the contagion out. In 36 cases of diphtheria complicating measles, there were but four deaths. This very limited mortality is due to early diagnosis and to the free use of diphtheria antitoxin.

While the death-rate of simple measles was 15½ per cent. that of the measles complicated by diphtheria was only 11 per cent. Measles is especially severe in very young children. Below

the age of two the death-rate was 36 per cent.; above that age it was only 5 per cent.

Koplik's Spots in Measles.—In 79 cases the careful examination of the buccal mucous membrane was made for Koplik's spots. In 76 per cent. of the patients they were found. In 20 per cent. of the patients they were noted before the rash on the body appeared. In one case it was four days before the cutaneous exanthem, in two cases it was three days, in four it was two days, and the average time of its appearance before the rash on the body was about 36 hours. Its appearance, however, it not sufficiently early to enable it to be of any prophylactic importance. Dr. Koplik himself has expressed the opinion that the early diagnosis of measles, made possible by the discovery of these spots, would enable hospital authorities to segregate measles cases before they have been any serious source of contagion to other children. This does not promise to prove true in practise. Considerably before the appearance of Koplik's spots the catarrhal stage of measles is already well marked. It is now generally agreed that the disease is especially contagious during this catarrhal stage and before the appearance of any exanthem. For the discovery of Koplik's spots good, bright daylight is absolutely necessary. A certain amount of experience in finding them is also a requisite. Frequently they will be missed by one not used to looking for them and be found only after repeated examinations. Observations made under gas-light are practically of no value in the matter.

Dr. J. Sobel said that he believes that Koplik's spots are always present in measles. He has seen a large number of cases, several hundred during the last two years, and in every case in which he has been able to look for them with sufficient care he has found the spots present. They occur from a few hours to five days before the eruption on the body. Where a measles-like disease occurs and these spots are not found the disease is probably German measles. These spots constitute the differential diagnostic sign for the two diseases. There are other signs by which German measles may be distinguished, although they are not so constant. German measles comes on more suddenly, that is, without the preliminary catarrhal period. There is usually less fever, from 99.5° to 101° F. The spots are concentric and crescentic in shape. There is a velvety feel to the skin and the posterior cervical glands are enlarged. Then, there is a lack of correspondence between the severity of the eruption and the illness of the patient. There may be a very widespread, abundant eruption and very little disturbance of the patient's feeling. German measles does not protect against the ordinary form of measles, and care must be taken that children that have had one are not needlessly exposed to the other. For the discovery of Koplik's spots a good light is absolutely necessary. Gas-light should not be used. The child's cheek should be thoroughly everted and direct daylight from an open window used.

Dr. J. Howland presented the statistics of 61 cases of measles at the New York Foundling Hospital. Altogether there were only four deaths. All pneumonia cases were specially quarantined from the other children as soon as the pneumonia was discovered. All of the deaths were among the penumonia cases. One of the reasons for the comparatively small mortality was the frequent cleansing of the wards. At the end of each week all the children were removed from a ward and it was freely carbolized and treated several times to the vapor of formalin. All of the measles cases were immunized against diphtheria by the injection of from 250 to 400 units of antitoxin. No diphtheria occurred. There was no noma, though there were three cases of very severe ulcerative stomatitis. There was also measles at the country branch and altogether in 51 cases Koplik's spots were carefully looked for. They were found in 84 per cent. of the cases. In one case, four days before the eruption on the body, in two cases three days before that eruption, in six cases two days before, in 15 cases 24 hours before, and in 20 cases just as the eruption appeared. In 7 cases they were not found until after the eruption on the body had reached its height. Usually about the time that the eruption on the body was at its maximum, the spots on the buccal mucous membrane began to fade and soon disappeared.

Dr. Milner said that Koplik's spots are especially valuable for differential diagnostic purposes. They enable us to recognize at once the eruptions that occur after antitoxin and to differentiate measles from German measles. Dr. Lipmann said that while the name, Koplik's spots, was a very proper one since Koplik's observations and writing had made them of practical value for the general practitioner, it must be remembered that Flindt had described them as early as 1880. Flindt had also noticed their presence on the conjunctiva in certain cases. Dr. Lipmann has recently seen a case in which the spots were on the conjunctiva. It is evident that for the early diagnosis of measles there is no better sign, and it should be made the duty of hospital interns in all cases where measles exist in a hospital to examine the mouths of the children carefully twice a day in order to segregate the measles cases from other children as soon as possible.

Recurrence of Measles.—Dr. Mabbot said that the occurrence of attacks of measles in 16 per cent. of the cases in Dr. Adriance's statistics seems entirely too high and he can only think that some source of error must exist. Undoubtedly cases of German measles are frequently mistaken for ordinary measles in reports of second attacks. Koplik's spots will especially be of value to the medical profession if they enable the general practitioner to differentiate these two diseases with certainty.

Dr. Mabbot described the system in operation at one of the hospitals in New York City by

means of which the Board of Health's Report as to the existence of contagious disease in any particular locality is made available to enable the hospital to guard against the admission of contagious diseases to its wards. A tabulated record is kept of the exact location of every case of contagious disease that is reported by the health authorities. Visitors who come to the hospital from infected houses are excluded. Each visitor is asked to give his or her address and it is the duty of the door attendant to note whether the address is that of a house in which contagious diseases exist. When patients apply for admission the same rule is put in effect. In this way the hospital is able to guard much more effectually than before against the admission of contagious diseases.

Dr. Kerley is of the opinion that measles does not protect from second attacks as much as has been thought. The predisposition to repeated attacks of measles seems to exist very distinctly in certain families. There is one family in which he has seen within this last year two children have two distinct attacks of the disease. In both attacks Koplik's spots were noted. The mother of the family, an extremely intelligent woman, has assured him that each of her other two children has had two attacks of measles and one of them has had three. It is a tradition in the family that the children acquire measles whenever they get the slightest opportunity.

Dr. Freeman said that he has seen measles run its course without Koplik's spots and that he has seen the spots where no measles existed and where the disease did not develop afterwards. It does not seem safe, then, to segregate children because of the spots alone, as they may thus be exposed to the disease at a time when they are not already infected.

Dr. Herman said that Koplik's spots were especially valuable to the medical inspector of schools. A careful examination of the buccal mucous membrane enables one to exclude children from school two and three days before the disease would ordinarily be discovered. A considerable amount of exposure of the other children at the school is undoubtedly saved by this means and the spread of an epidemic of measles greatly diminished.

REVIEWS.

A Pocket Text-Book of Theory and Practice of Medicine. By George E. Malsbary, M.D., Assistant to the Chair of Theory and Practice of Medicine, Medical College of Ohio, Cincinnati. Illustrated. New York and Philadelphia: Lea Bros. & Co., 1899.

A book on the practise of medicine must indeed be very extensive to include all the facts and data which have been added in the last decade, and nothing short of voluminous and comprehensive systems of medicine can fulfil every indication for a complete work on the subject. This handbook, which is included in the series of pocket text-books, is an excellent little work and is an admirable exposition of the subject dealt with. It is pleasant reading and will appeal to every student and general practitioner who wishes to consult a ready reference book on medicine. The chapters on infections, intestinal and blood diseases are full of instructive details. It covers the entire subject of general medicine and is thoroughly modern, and is written in a careful and pleasing style. This volume we are sure will find favor with the profession.

An Introduction to Dermatology. By Norman Walker, M.D., Fellow of the Royal College of Physicians of Edinburgh. New York: Wm. Wood & Co., 1899.

This work is exactly what it claims to be, namely, an introduction to the study of dermatology. It covers the subject of skin diseases in a very comprehensive manner, and, while making no pretension to exhaustiveness, it nevertheless treats of the various lesions fully enough to enable the student and general practitioner to acquire a very good knowledge of them.

A good deal of attention has been paid to the histopathology of the more important diseases and the most cursory examination of these parts shows the author to be a man who is well acquainted with the latest scientific work in his specialty, and with the most recent theories.

The book is profusely illustrated. Some of the plates are in colors, and although the majority cannot be said to be very truthful reproductions, they still give the reader some idea of the appearance of the various lesions.

Treatment of Ozena.—During the winter months the patient should take cod-liver oil, or, if this is not well borne, the following mixture:

℞ Ammonii chloridi .....gr. xv
Potassii iod .....ʒi
Syr. gentian .....ʒviii
M. Sig. One tablespoonful twice a day.

Or, he may instead, take from 1 to 20 drops of a 1 per cent. solution of iodide of arsenic, the dose depending on the age of the patient.

If hereditary syphilis is suspected, the medicine should be ordered accordingly. It is advisable to make a change in the irrigating fluid from time to time, say once a month, sometimes usin gthe following, recommended by *Moure.*

℞ Ac. carbolici .....ʒvii
Glycerini .....ʒiiiss
Spiritus (90 per cent.).....ʒii
Aquæ .....ʒxii
M. Sig. One tablespoonful to the liter of tepid water.

AN IMPROVED OPERATION FOR ACUTE APPENDICITIS OR FOR QUIESCENT CASES WITH COMPLICATIONS.

BY ROBERT F. WEIR, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

HOWSE, in 1879, was among the first to split, rather than cut, the muscular layers of the abdominal wall in an endeavor to secure a sphincter effect in an artificial opening into the alimentary canal. While this was imitated by many surgeons in the rectus muscle when a gastrotomy was resorted to, it was more nearly perfected by Maydl in 1888, when he planned an intermuscular separation in connection with the establishment of an artificial anus in the left iliac fossa. But no one resorted to this procedure for entering the abdominal cavity for operative work with a view to secure thus, from the subsequently replaced muscles and their fascia, a restored abdominal covering that would effectually prevent the occurrence of hernia until the efficacy of this method was made known to the profession by McBurney, in 1894. The test of experience has fully confirmed the judgment of this surgeon, who considered it as applicable to the ablation of the appendix in a state of quiescence from a still unquenched fire. It yet remains as the operation *par excellence* for this class of cases, and a recent experience has confirmed to me its utility in a manner that is not common. In a patient who had been operated upon by the McBurney method (*i.e.*, muscle separation after dividing the fascia of the external oblique for a distance of about three inches and then transverse division of the transversalis fascia and the peritoneum) for a supposed chronic appendicitis, and from whom a kinked appendix was removed, a second laparotomy was afterward demanded for the continuance of pain which, as time went on, revealed as its cause an enlarged right ovary. This was performed nine months subsequent to the first operation. The second skin incision was parallel with and close to the first, and on exposing the fascia of the external oblique muscle, save at one or two slight points where the skin adhered cicatricially, no trace whatever of damage was to be found in the fascia itself even when widely exposed, nor was there in the muscular layer, when hunted over in the new separation, to be found more than occasional traces of increased connective tissue. Had one not been on the lookout, it might have been supposed to have been a virgin operative field.

McBurney's limitation of this operation to those cases where inflammation was absent or where its traces were slight, as far as external evidences went, has been shown to be a wise one. For, as all operators know, even in the so-called quiescent stage the appendix may be bound down with adhesions or abnormally displaced, or even at times be associated with unexpected, although small, suppuration about or near it. These complications would occasionally demand more room than that which would be obtained by stretching the separated vessels from the iliac spine to the edge of the rectus muscle. This space will seldom average more than two inches in transverse width, although the opening can be pulled down to a little greater width in a vertical direction. Increased space was obtained to meet these conditions by other surgeons who endeavored to use the excellent method in acute cases of appendicitis by incising the median end of the intermuscular space upward along the edge of the rectus. This certainly gave more room, but the abdominal wall was correspondingly weakened and its repair could not so satisfactorily be obtained by the buried sutures that were necessarily applied. My own experience in this enlargement was not a satisfactory one and for some time I balanced in operating for acute appendicitis between the old incision through all the tissues of the abdominal wall and the enlarged (and hence much deteriorated) muscle separation method.

Some two years since, being led to it by the experience obtained since 1894 in the oblique incision for gall-stone surgery, wherein additional room was had by incision of the rectus sheath, drawing the muscle to the median line and then dividing the posterior fascia, I ventured to increase the intermuscular space of McBurney by similarily treating the rectus at this lower level. I was at first hampered by the difficulty of dragging the median edge of the divided fascia of the external oblique sufficiently far inward to expose amply enough the anterior sheath of the rectus muscle. For the past six months the procedure has been simplified and made more desirable by tearing off, with the finger-tips or with the end of a blunt scissors, the already denuded fascia of the external oblique muscle from the sheath of the rectus quite up to the median line where it is held retracted by an assistant. The anterior sheath of the rectus is now divided transversely in a line continuous with the opening made in the peritoneum by the original muscle separation operation. The outer edge of the external rectus muscle is then lifted up with a director or the end of blunt scissors and carried by a retractor also to the me-

dian line or as near as may be desired. On the thin transversalis fascia, with the peritoneum underneath it, that here makes up the posterior sheath of the rectus will be seen the epigastric vessels which should be seized, divided and ligatured and sometimes pulled outward, and the sheath and peritoneum cut in a manner similar to the outer sheath. When blunt retractors are now passed into the peritoneal cavity and the abdominal wall put on the stretch, there is a very superior exposure of the whole pelvis and of the right iliac fossa. Indeed, I have never before been able to command these parts so well until exposed by the incision, and particularly is it so if the gravity action induced by a sand-bag under the right hip or by a Trendelenburg position judiciously used after the removal of infecting inflammatory fluids.

During the past year I have systematically used this operative procedure in twelve cases. In three of these there were unlooked-for complications in the removal of a quiescent appendix. One was a tubo-ovarian case, already alluded to, and the other a case of ectopic gestation, wherein the first attack of pain one month before the second was associated with a tumor in the appendicular region and in which in the last attack the ordinary evidences of hemorrhage were not marked and the symptoms pointed simply to an appendicitis. Here the removal of the three-months' fetus and sac and of the numerous clots was most readily accomplished and the necessary irrigation of all parts of the abdominal cavity obtained by the wide space given by the rectal sheath incision. In all of these five cases the wound was tightly and promptly closed, first by sewing together, with No. 1 catgut, the posterior sheath of the rectus with its continuation outward of the transversalis fascia and peritoneum up to its outer angle near the anterior superior iliac spine. Then the rectus muscle was dropped back into its place, its front sheath closed by interrupted sutures of chromicised No. 1 catgut, a special suture fitting neatly the outer border of the sheath. After this the abdominal muscles were allowed to come together and held generally by one or two simple No. 0 catgut stitches and, finally, the incised fascia of the external oblique is closed with a similar catgut continued suture, and the skin brought together with fine black silk interrupted stitches. Not only the anticipated primary union has occurred, but from no damage being done to any of the nerve supply of the rectus muscle, no bulging or weakness of the abdomen has been produced.

Of the seven other cases there was in six more or less severe suppurative or gangrenous appendicitis and in one so extensive a peritonitis showed itself that it might have been classed by some as general, but being somewhat skeptical about cures in such forms of peritonitis and from the scattered but well-formed lymph patches that were present, I considered it an extensive but not a general invasion of the abdominal cavity. For its treatment after the amputation of the gangrenous and perforated appendix, a nearly complete evisceration, cleansing and irrigation with hydrogen peroxide solution of the major part of the small intestines were undertaken and free irrigation and wiping with one-yard pieces of gauze of the partly emptied and fully exposed peritoneal cavity. The wound was then closed as narrated, save that in this case as well as in the five others, a space the size of a quarter-of-a-dollar or less was left in the various layers of the abdominal wall at about the middle of the skin incision through which were carried wicks of iodoform covered by thin rubber tissue (not gutta-percha, as this easily breaks off) to allow of easy withdrawal. The peritoneum, fascia, and muscle were closed by suture up to the drain. A provisional suture of chromicised catgut is occasionally left to close the opening a day or so after the withdrawal of the drain. More time is required to test the value of this extension as to hernial protrusions which are stated by Coley to occure once in twenty times in the older style of cutting through the entire abdominal wall and in which drainage is used. Even although little or naught should be gained in this direction, which I cannot think possible, the great advantage obtained by the full exposure of the central part of the pelvis and abdomen must enable a surgeon to care much better for infectious lesions now often beyond his ken.

It is further believed, since Abbe has shown that the kidney can be reached by intermuscular separation, that with this utilization of the rectal space, plus the muscular separation, more ease of surgical work can be attained in liver and gall-stone surgery. Bevans' access to these regions is largely due to the use of this means.

THE BUBONIC PLAGUE.[1]

By EDWIN KLEBS, M.D.,
of Chicago, Ill.

With the enormous disasters resulting on the widespread extent of the bubonic plague in medieval times and especially in the English-speaking countries in the seventeenth century in mind, it is hardly surprising that its occurrence should be dreaded at the present time, especially when it is remembered that this plague still devastates Asia, and that improvement in travel promotes the spread of germs. The question whether a recrudescence of the plague in Europe is likely to occur can only be answered after an analysis of the better known conditions of the biologic character of plague germs and of the clinical aspects of the disease in man and animals. Knowledge of the first practically began with the determination of the plague bacillus (Bacillus pestis bubonicæ) by Kitasato and later (1894) by Yersin. In the preparation of the present lecture I have analyzed for data about forty papers upon the subject in order to furnish facts which will be of assistance in determining methods of ascertaining the danger of this plague and the means of combating it. In discussion of these questions the cause of the bu-

[1] Read before the Chicago Medico-Legal Society, December 2, 1899.

bonic plague must be considered first; second, the disease, and, finally, prophylaxis and therapeusis.

The plague bacillus has been demonstrated beyond a doubt to be the cause of bubonic plague, since every phase of Koch's law has been fulfilled by it. The bacillus pestis bubonicæ has a small, rod-like appearance. It is one micromillimeter in thickness and from three to five times this dimension in length. Under favorable conditions, in fluids, it forms chains, every link of which, dividing repeatedly, produces diplobacilli. If the growth be rapid there are formed coccus-like varieties. If the temperature is too high or the nutrient medium is not perfectly adapted there arise degenerative or monstrous forms which serve a useful purpose in diagnosis. They can be produced for that purpose, as has been recommended by E. H. Hankin of Aga, India, if cultivation be made on agar containing two-and-a-half to three-and-a-half per cent. of sodium chloride. It is easier, however, to raise the bacilli first upon the usual pepton-agar and later transfer it to the salt agar (Hankin and Leuman). These degeneration forms are not endowed with lesser power of infection than the regularly grown forms. They seem partially affected by plasmolysis, forming large round, oval or club shaped bodies, often clostridium-like; sometimes they present large and irregular masses, threads, branched forms and networks and seem to consist of a gelatinous substance excreted from the organism. This substance is frequently found in older cultures of the plague bacillus in the form of round globules of different dimensions staining very deeply in dilute carbolfuchsin.

In a culture which I received from Kral of Prague, these forms were abundant and were in puzzling appearance contrasted with the more lightly colored bacilli. It has not yet been ascertained whether these forms are also present in bubonic pus, but it has been noted that the pus of buboes seems to contain cocci which may be a misinterpretation of the presence of the globules.

Staining of the plague bacilli may be effected by alkaline analine dyes, but is never very intense; if not, polar globules are present, which is not the case in every culture. The plague bacillus grows best on normal agar and gelatin media without addition of glycerin on sugar. It forms in the stab and streak, first transparent colonies, which later exhibit a whitish, then a yellow tinge, and then become granulated. The larger forms are surrounded by a slight iridescent area. The most favorable temperature is seemingly somewhat under 36° C. Kitasato was of an opinion that this bacillus was mobile but later observers deny this. My cultures not being fresh ones cannot settle this question. The plague bacillus is most readily demarcated from cocci by decolorizing in the Gram treatment, by the absence of spores and by the degeneration forms. Gabritschewsky has seen capsules stained with Loeffler's blue, whereas the bacilli were stained red by carbolfuchsin. This may be the commencement of degeneration or formation of the glutinous substance.

The general belief is that the plague bacillus is easily destroyed by drying and cannot live a long time in water. There are observations which seem to show the contrary. Kasanski found that the bacillus lived in the water of the water supply of Kazan from ten to forty-eight days; in milk twenty-six and in urine sixty-two days. His observations have been confirmed by W. E. Abel both as to sterilized and non-sterilized water. Nadjesda K. Schultz, working under supervision of Nencki claims to have found spores in a culture on addition of a small quantity of phenol. The plague bacilli, according to C. P. Gladin, do not die readily on drying. He found that in drying them on cover-glasses in a temperature of from 14° to 24° C. they lived from one to nine days. Dried upon silk threads, they lived from one to twenty-one days; upon thicker cloth, fourteen days; upon rough linen twelve to twenty-six days. It is generally conceded that the plague bacillus, in fluid media, is readily killed by heating it to 58° or 60° C. Toptschieff found that it was killed in test tubes by heating at 58° C. for eight minutes and in capillary tubes for four minutes. Temperatures below zero are very well borne by the plague bacillus, according to Kasanski. This may explain why epidemics in warm countries are more dangerous in winter than in summer; although there are exceptions to this rule.

Disinfection by chemicals kills the plague bacillus very quickly. According to Hankin they are killed by a two-per-cent. solution of carbolic acid in two minutes, mercuric chloride, 0.2 per cent., and copper sulphate, 0.1. The bacillus is more resistant to alkalies than to acids. Acids are very effectual. Hankin saw the bacillus die in one hour in sour milk. This may be the effect, however, of milk bacteria which act in destroying similarly to the micro-organisms of decomposition. According to Hankin the death of the plague bacillus occurs in organs in six days. Yokoto, however, found that they still survive in the dead bodies of animals at a temperature of 22° to 30° C. for fourteen days; and at a temperature of 10° to 22° C. for from nineteen to twenty-two days. Schotteli found that evidences of the bacillus from buried plague-stricken animals very rapidly appear in the surrounding earth. Calcium chloride and potassium permanganate are very effective according to Hankin in one-tenth-of-one-per-cent. solutions. According to N. K. Schultz, mercuric chloride (1 to 1000) is very effective in two minutes; mercuric chloride with hydrochloric acid (1 to 20,000) is effective in the same time. Formaldehyde and phenol, but only in the concentration of 1 to 50, kill cultures in two minutes. The first, however, acts excellently as a gas.

With reference to the disease produced by this bacillus known as the bubonic plague, I shall vary its description from that given in the ordinary text-books, not only because these are well known but also because the variation is needed for the purposes of State Medicine. For this purpose the different ways in which the bacillus can be introduced into the body will be first discussed. In by

far the majority of cases there is a close connection between cases of plague and new infections. In some instances such a connection has not been demonstrated, as was the case in ten patients studied in a Bombay hospital by H. F. Mueller, who died plague-stricken from his later work in Vienna. From his results it appears that plague infection may occur without lesion of the skin (the generally accepted origin of the primary bubo) and seemingly without other direct contagion. The possibility of infection by insects, demonstrated first by Roux, must be taken into consideration in such cases. He found that flies caught in the laboratory of the Pasteur Institute of Paris, in 1897, where work upon the plague bacillus was done, if ground in sterile water, infected guinea-pigs with plague. It is, therefore, obvious that these insects may also disseminate the virus. In one case described by Mueller in a hospital not containing plague patients, a man with testicle and lung tuberculosis developed a cubital bubo at the eleventh day of his stay. From this he subsequently recovered.

While the German Commission denies that fleas and mosquitoes can infect with plague, still there are many observations which demonstrate this. Hankin found the plague bacillus in fleas and ants which had been on rats dead from plague. Simond infected living rats by the fleas from rats killed by plague. Without fleas such rats were proven non-infectious. The German Commission, however, denied this method of infection so far as regards man. Indeed, it does not seem very probable that fleas infesting rats will attack men. Against the infectious action of fleas from plague-stricken patients stands the fact that in the wards of the Bombay hospitals, visiting and working people rarely if ever became infected.

The expectoration of pest pneumonia has much greater tendencies to disseminate plague germs in a spray formed by small drops containing air (Fluegge). Such patients should be isolated and covered entirely with a veil supported by a light frame. The physician should guard against this mode of infection but not, as was advised by the Imperial German Health Board, in October, 1899, by the use of thick veils which cover the face and impair sight and respiration. In lieu of this, sterilized gauze should be always ready in the side pocket for use in covering the mouth and nose in an emergency. Sublimate gauze was used for this purpose in the cholera barracks in Hamburg. The danger, however, is much greater in plague. It should not be forgotten in the treatment of plague, to clean the mouth and nose from time to time with disinfectants, since, as has been shown by the German Commission in India and by Baizaroff, the slightest infection of the nose may give rise to plague pulmonary disorder. Physicians and people who have to do with plague patients should cut off their beards and disinfect the whole surface of the face, especially the former hairy parts. They should then gargle with and swallow non-poisonous disinfectants.

The possibility should not be forgotten that infection may occur through water and food. In time of epidemic boiled water and cooked food should be employed and scrupulous cleanliness should be enforced.

For therapeutic and prophylactic purposes experiments in bacteriotherapy have been made. Haffkine employed for therapeutic purposes cultures killed by heat and kept sterile by addition of carbolic acid. Heat according to Markl partly destroys the toxin. Haffkine's work has been sharply criticised by Bitter who, however, concedes that some good results were obtained by Haffkine despite the unhygienic methods employed. In families, some of whose members were vaccinated, Bitter found that the non-vaccinated (124) had forty-three-and-a-half per cent. of plague cases with sixty-and-a-half per cent. of mortality, while the vaccinated (250) had but twenty per cent. affected with but eight per cent. mortality. The continuous contact of the non-vaccinated, as Haffkine remarks, must have exerted an unfavorable influence on the vaccinated. The Imperial German Health Board has recommended the erection of stations for the production of antiplague vaccine. Yersin has had by no means disappointing results with antiplague serum. There seems, however, to be some difficulty in reaching a higher degree of immunity in horses; a difficulty which further study will doubtless overcome. In Amoy the mortality of twenty-three cases treated with serum of Yersin was but seven-and-half per cent. against the sixty to ninety per cent. mortality so frequent in epidemics of the plague.

The first method of combating the spread of the plague must be by general hygienic measures. These measures following the conclusions of the Imperial German Health Board should be as follows: (1) The control of transportation of persons and of merchandise. This should include careful observation of the suspicious cases with retention of the sick for a sufficient time for medical study. It should also include quarantine against plague-stricken countries for a period of ten days, which can be shortened or omitted if a sea voyage of more than ten days has preceded the arrival of the vessel. (2) The proper education of experts, which will include the thorough training of bacteriologists in the life-history and culture of the plague bacillus and also educational courses for sanitary officers. (3) The measures which should be taken in the event of the appearance or suspicion of appearance of a bubonic plague, as follows: All suspected plague cases should be immediately notified to the proper authorities. All pneumonias should be regarded as suspicious and also notified; this procedure has long been adopted in English-speaking countries in principle, in the notification of diarrhea cases during cholera epidemics. Where suspicion of a case occurs, a sanitary expert should be immediately sent. Portable laboratories should be instituted for use in such emergencies. The demonstrated cases of plague should be isolated immediately in a plague hospital. If the case of

plague has originated spontaneously and there is reasonable suspicion that rats are the source of infection, the whole house should be cleared (Pfeiffer). If the case, however, be imported, the flat alone should be cleared and the well members of the family should be kept under observation in other quarters. Gaffky found it sufficient to submit the well members of the family to daily medical inspection while permitting them to move around freely.

In regard to the question of disinfection, Fluegge claimed that his method with formalin-steam could be used even if the windows and doors were not hermetically closed. In this event three times the usual quantity of formalin would be needed. As already observed Schultz has also found that formalin in gaseous forms possesses great efficiency. The nature of protection needed for physicians and nurses has already been discussed. In the struggle against the rats, Frosch advises strychninized-wheat, which in Oporto has given good results when laid in sewers and canals. It is well known to sanitarians that sulphurous acid used in fumigation drives away rats. The German steamers which land in plague-stricken places put large sharpened discs upon the cables connected with the pier as defenses against rats. It seems desirable that special institutions should be erected by the Government for the purpose of securing preventative and healing injections. For active immunization of animals with living cultures such institutions should be placed on islands, as is done in Russia and in Italy. It is further recommended to employ for the production of the preservative substance, or vaccine, a combination of active and passive immunization, since the last process is low in action but diminishes the reaction of the first. By passive immunization is understood in Germany serum treatment. The French scientists (Calmette) substitute for these expressions the somewhat less obscure phrase "cellular and humoral immunization." As Loeffler very correctly remarks, passive humoral immunization may not prove sufficient against infecton of the respiratory tract. With reference to the danger from dead bodies in plague, Fluegge is of the opinion that this is not great, but ignores the observations previously cited from Shottelius, and also the fact that plague broke out in Egypt after disinterment of the bodies of the Arabs killed in the battle of the Pyramids.

If the conditions which are known to exist anent the bubonic plague, its nature, its method of spread, and the conditions which give it an epidemic character be considered, the danger for the United States does not seem very great. It should, however, be remembered that the Western Hemisphere is no longer free from the plague. Importations of it have already taken place in New York. The battle against its further spread will be successful only if uniform hygienic measures are instituted throughout the whole country. This cannot be done without supervision from the Federal Government. More than ever before, is is evident that a Department of Health should be created in the Cabinet of the President, such as has long been advocated by the medical profession. In the larger cities, such as Chicago, proper cleansing of the streets, proper drainage, such as the drainage canal will ensure, and the institution of more effective disinfection are required. The medical profession will certainly help the local governments in every way if opportunity will be given.

Discussion.

Dr. Gehrmann, in expressing his appreciation of the remarks made by Dr. Klebs, said: The two points which seem to be of interest at the present time, while the plague is still distant, are the different ways in which propagation takes place and the diagnosis of cases. The relation of the smaller animals and insects to the spread of the disease is one of the latest demonstrations. In *La Semaine Médicale* there recently appeared an account of ancient pictures where a number of rats and mice are figured in the area where the patients were, the attempt being made to show the relation of these animals to the disease. The experience in India and Continental Europe seems to show that the most severe outbreaks occur in the outlying and shipping districts, and that people become infected in warehouses in connection with the handling of goods coming from foreign countries. From these people it is transmitted to residence districts and from these it spreads. Rats also bring the plague, and their access to warehouses is again one of the factors in distributing the disease. These people are subjected to infection of the worst form; the condition of these buildings, damp, and with little chance for the admission of sunlight, seems to assist the spread of the plague by lessening their resisting powers.

The various details laid down, as reported in the Berlin Conference, should make it comparatively easy to recognize cases of plague. There is some difficulty in that the bacilli do not retain their activity in the glands throughout the length of the disease, making their isolation quite difficult, but, as Dr. Klebs has said, extensive experiments show that there is no reason why the bacillus cannot be isolated. The characteristics of the bacillus are not wholly settled; the main features, however, are determined.

From the literature it seems that the possibility of infecting animals by feeding them plague material ought to be one of the very important diagnostic points; that where we have cultures, or material suspected of containing the plague bacilli, the feeding of this material to rats and mice and thereby infecting them, as well as by direct inoculation, would be a very valuable point. At present our reliance must be placed in the vigilance of our Marine Hospital Service to prevent importation of plague cases into this country.

The instructions recently issued by Surgeon-General Wyman if intelligently applied by the officers of the Marine Hospital Service will insure our country against invasion by this pest.

A CONSIDERATION OF ACUTE INFLAMMATORY RHEUMATISM.

BY W. H. NEILSON, M.D.,
OF MILWAUKEE, WISCONSIN.

INFLAMMATORY rheumatism is a disease with which we so frequently come in contact, and about which we know so little, that papers upon and discussion in regard to it can only do good, if it be only to fix in our minds how little we know about the subject—how circumscribed are our limitations. If this much can be clearly defined we have made a distinct progress, for one of the first requisites towards advancement in knowledge is to unlearn much that we think we know.

There is probably no disease with such prominent symptoms and so easy of diagnosis as inflammatory rheumatism, and yet none that has been burdened with so many theories as to its etiology and methods of treatment.

From the active antiphlogistic treatment of the ancients to the whey expectant treatment of Sydenham 200 years ago, to the return to active blood-letting and purging of the eighteenth and early nineteenth centuries, to the formulating of the lactic acid theory by Prout, to the disappointment of the alkaline treatment leading to the placebo of our own Flint, and the mint waters treatment of Sutton in 1863-5, down to early in 1876 when Maclagen gave the results of the salicin treatment to the profession; and a little later to the favorable reports of Stricker and Riess on the employment of Kolbe's synthetical product, salicylic acid, the history of the treatment of inflammatory rheumatism has been marked by thereapeutic monstrosities, blindly worshiped until smashed by some iconoclastic scientist, who then sets up some other idol whose crown appears to be of the pure metal, but whose feet are crumbling clay.

Loss of faith in methods of treatment resulted from time to time in the agnosticism of the placebo, the whey and the mint water; and a study of the devotion, the revulsion, the indifference of the mind of the profession during these centuries, would make an interesting chapter in psychology. Not until 1876, when the reports above referred to were published, was there any distinct thereapeutic progress made. Treatment based on the old theories was found unavailing. One by one the hypotheses were found to be inadequate to explain the conditions present, until, finally, the resemblance of inflammatory rheumatism to malaria engendered the belief that it was of miasmatic origin, and that salicin was its natural antagonist.

That after the lapse of twenty-three years our mental attitude should still be one of belief and not of conviction is proof of the difficulties of investigation and a sad commentary on our scientific limitations. That we are tsill hampered by much of the lumber of the past is undeniable and our progress is by that much impeded. Phlogiston is still a shadowy factor in deciding our treatment; there are still ill-defined shapes of acids floating before our mental vision, affrighting us by their very indefiniteness, and, perhaps the veriest bugaboo of them all, the nervous system, challenges our attention; and yet with it all, true progress has been made, not only in the therapeutics, but in the etiology of inflammatory rheumatism.

Inflammatory rheumatism is a disease of the serous and fibrous tissues of the body, especially manifesting itself in those which are concerned in facilitating, limiting, and producing motion, *viz.*, synovial membranes and the left endocardium, the ligaments of the joints, tendons and muscles. That no fibrous or serous tissue is exempt from the rheumatic poison is generally understood, but the chief manifestations are restricted to the structures mentioned.

The disease is characterized by pain, which is present until the disease is cured, by swelling, heat, redness, and impairment of function, the cardinal points of inflammation—an inflammation, however, which seldom results in the formation of pus. It is, furthermore, characterized by a temperature of a variable character, by a somewhat regular progression of the inflammation from one joint to the other—the accession in one joint often being accompanied by recession in another, by various nervous symptoms, oftentimes nausea and constipation, scanty urine loaded with urates and some crystals of uric acid, lactic acid in the blood, a profuse acid sweat—which acidity some claim to be due to lactic acid, others to putrefactive changes on the surface, or to the elimination of volatile fatty acids—and in some cases urticaria, purpura, erythema, eczema and nodes.

To account for this complex of symptoms, many ingenious theories have been formulated and foisted upon an ever-ready profession, only to be found lacking in some essential. The theory which has had the strongest hold upon the profession is that lactic acid is the cause, and that this idea still has many adherents is witnessed by the untiring efforts of the pharmacists in exploiting the various antacids. That lactic acid is found abundantly in the blood of patients suffering from this disease is demonstrable; that its excess is eliminated by the skin, causing the profuse, perspiration, instead of by the usual route of the lung as water and carbonic acid gas, seems highly probable, but that a constantly present chemical agent can produce the irregular symptoms present cannot be believed.

Physiologists tell us that lactic acid is a result of muscular waste, whether that be brought about by exercise or by cell activity induced by irritation; that fibrin, which is in excess in the blood of rheumatics, is produced in the same way, the one from the glucose of the muscle; the other, with urea and uric acid, forms the nitrogenous elements. We are told by the adherents of this doctrine that an excess of lactic acid as the result of severe exercise is made patent for

ill by exposure to cold. We cannot conceive of enough of the acid being produced in this manner to keep up a protracted, violent attack, the symptoms often increasing in severity when there is free elimination through the skin, nor that fresh joints frequently should be involved even after weeks of protection from cold in a comfortable room and a warm bed. We cannot conceive of a reservoir for the holding of the acid from which it is given out in accordance with the severity or mildness of the symptoms. Any tenable theory of a disease must adequately explain its phenomena. The lactic acid theory measured by this cannot hold; no more can the nervous theory, although to the pathologists it has much that is alluring.

When considering the miasmatic theory, we feel that we are on firmer ground. Although, notwithstanding twenty-three years of research, much is involved in obscurity and nothing in a biologic way has absolutely been determined, yet the clinical facts point so unerringly to bacterial development, and above all the therapeutics have so decided a limiting effect upon the disease, that we are forced to admit a partial correctness of the belief now steadily gaining ground. Bacteriologists have demonstrated that micro-organisms have the quality of selecting their proper habitat or nidus; that their activity depends largely on their supply of nutriment; that when their nidus is exhausted their activity ceases; and that their presence in tissues under proper conditions provokes inflammation which will continue as long as the irritant is active.

Granted we have the micro-organisms finding an entrance to the body with all the conditions right, their particular nidus is the serous and fibrous tissues. As a result of their activity inflammation supervenes, only to die down when the nidus is exhausted; new colonies are sent out to invade fresh fields of fibrous or serous tissues; the fields of first invasion are renewed only to be attacked and occupied by another colony, and this indefinitely, as is a matter of clinical observation, unless checked by treatment.

Micro-organisms in their growth use up water and nitrogen, thus accounting in part, at least, for the thirst and wasting. Their presence in the muscular, fibrous and serous tissues induces active changes, such as inflammation, lactic acid, uric acid, urea. Lactic acid induces profuse perspiration, which can be experimentally demonstrated; urea and urates are abundantly found in the urine, which is scanty on account of the loss of water. New colonies invading new fields produce fresh inflammation, and exhausted fields renewed furnish pabulum again. Thus does this theory explain the symptoms of inflammatory rheumatism. But we do not have to rely on theory alone, for as a result of observation it has been pretty thoroughly demonstrated that the presence of micro-organisms is an etiologic factor of importance.

Achalme has repeatedly found a bacillus both in the living patient and post-mortem, cultures of which induced joint-swelling in the guinea-pig. Boucheron, in addition, has found staphylococci and streptococci and has seen good results in six cases from injection of Marmorek's serum. Thiroloix found a bacillus which grew abundantly, was slightly motile, and which he claimed to be identical with Achalme's. Maragliano has also found micro-organisms in the blood of rheumatic patients. Numerous observers have found streptococci and staphylococci, and the frequent associations of rheumatism with tonsillitis and wounds lend color to the belief that the micro-organisms have their port of entry through the tonsils and through wounds. Above all, however, is the therapeutic proof, *i.e.*, the free administration of salicin, salicylic acid, or its compounds. It is a clinical fact that full doses of these drugs will cut short an attack of inflammatory rheumatism, and they do not do so by neutralizing the acid, for that is demonstrable even after all pain and fever have subsided.

The complications, too, bear the mark of infection, and we can hardly account for the blood dyscrasia which permits purpura and hematuria by any other hypothesis. But in accepting the infection theory of the cause, we must not lose sight of the fact that there must be a proper soil for the development of these micro-organisms.

What conditions are necessary to make the soil fruitful to bacteria of this particular sort we are not prepared to say, except that subjects of inflammatory rheumatism possess that peculiar predisposition towards disease known as the arthritic diathesis, that they suffer from the so-called acid-dyscrasia, and are individuals whose metabolism is subject to retardation. Oxidation in the tissues not being carried on to completeness, a great number of acids instead of the end products are the result, *i.e.*, water carbon dioxid, urea, uric and hippuric acids. As the result of incomplete changes in the digestive tract and of bacterial activity, various other acids are produced from the ingesta and find their way into the circulation, rendering the blood subalkaline, and it would appear that this subalkaline blood renders the tissues a fit culture medium. Then, through depressing agents, such as cold, worry, over-exertion, the resisting power is lost and the disease begins. The arthritic diathesis is undoubtedly inherited, for we see many manifestations of it cropping out in the different members of the same family or various signs of it in the same individual. That it can also be acquired is generally conceded. It, therefore, seems rational to forestall acute attacks by a line of treatment which increases metabolism, favors oxidation and prevents the development of the acids alluded to. As a clinical fact, prophylactic measures along this line are successful.

Of more than passing interest are the various complications we have to deal with, chief of which is endocarditis, occurring in one-third of all cases, also myocarditis and pericarditis, safe rules for the treatment of which are laid down in the text-books. Purpura rheumatica, peliosis

rheumatica, urticaria, etc., are interesting, as they show blood dyscrasia and involvement of the vasomotors. In these, in addition to the antiseptic treatment, iron and strychnine are indicated, and strict attention to the digestive tract must be maintained. Meningitis is not so infrequent and is not always attended by hyperpyrexia. When it antedates the joint involvement, as I have seen it do, the diagnosis of rheumatism is well-nigh impossible. It yields, however, if at all, to salicylic treatment in connection with ice-bag, bromides and chloral.

Pneumonia is always a serious complication and frequently is fatal. Salicylic acid, strychnine and digitalis must be relied upon. Hyperpyrexia is best combated with the Brand cold bath, giving stimulants if necessary. Nausea is a serious condition and often forbids medication by mouth. Inunctions of methyl-salicylate with lanolin can here be employed with good effect. After the acute symptoms have subsided the anemia and debility must be combated in the usual way, and by keeping in mind the infectious nature of the disease our restorative treatment will be guided accordingly.

To sum up: I believe that inflammatory rheumatism is an infectious disease; that its natural history points to this, its complications point to it, and the treatment found so effective proclaims it.

I believe that in salicylic acid and its compounds, we have an effective means of combating the disease, but if we expect results we must give it in full doses; that only grave albuminuria is a contraindication to its use, and possibly that objection is more fancied than real. No doubt the day is not far distant when the complete etiology of the disease will be known and perhaps then a better mode of treatment will be evolved. Until then we must hold fast to what we have, knowing full well that the present-day treatment, judged by its effects, holds a distinct supremacy over all its predecessors.

TWO CASES OF RUPTURE OF THE RIGHT LOBE OF THE LIVER; LAPAROTOMY. RECOVERY.[1]

By H. BEECKMAN DELATOUR, M.D.,
OF BROOKLYN;
SURGEON TO THE NORWEGIAN, LONG ISLAND COLLEGE AND ST. JOHN'S HOSPITALS.

Rupture of the liver is one of the rarer injuries demanding surgical interference. It is, likewise, accompanied by a high mortality, placed by Mayer at 86.6 per cent. and by Edler at 85.7 per cent. The high mortality is due to the severe shock and loss of blood and to the lateness of operative interference.

The two cases I have the pleasure to report came under my notice within about a fortnight of each other, and have many points of common interest. In both cases there was a direct blow over the right side of the trunk with a rupture on the under surface of the right lobe of the liver, evidently due to bending of that organ. In both, the immediate shock was so great that operative intervention was impossible for a number of hours. At operation in each case the abdominal cavity was filled with fluid and clotted blood, the hemorrhage having ceased entirely in one case, while it was merely an oozing in the other, at the time of operation. Both cases made an uneventful recovery and are now, two and a half years later, enjoying good health.

Case I.—Female, twenty-one years of age, on May 30, 1897, was violently thrown from a tally-ho, which was struck by a rapidly moving train. She was received in St. John's Hospital, Brooklyn, some four hours later. At that time shock was extreme, pulse almost imperceptible, skin anemic, and patient semi-conscious. It was evident that in addition to the shock a severe internal hemorrhage had taken place. There were several fractures of the extremities and fracture of the ninth and tenth ribs on the right side. Examination of the abdomen showed some distention and flatness in both lumbar and inguinal regions. The catheter withdrew from the bladder about three ounces of nearly pure blood. Active stimulation and infusion were resorted to. The following morning the patient's general condition was slightly improved; the catheter evacuated about six ounces of slightly blood-stained urine. It was decided to make an exploratory operation and this was done on June 1st, eighteen hours after receipt of the injury. After thorough preparation of the skin of the abdomen, and under ether anesthesia, a median abdominal incision was made just above the umbilicus. Immediately the peritoneum was opened there escaped a large quantity of fluid and clotted blood, estimated at two quarts; the hand was then introduced and the liver explored. A rent, two and one-half inches long and an inch and a half deep, of the under surface of the right lobe could be plainly felt and by extension of the incision slightly upward it was exposed. On viewing this it was discovered that all active hemorrhage had ceased. Further exploration revealed several small ruptures on the surface of the spleen, but from none of these was there active hemorrhage. The blood and clots were then rapidly removed from the peritoneal cavity and the abdomen left perfectly clean. The abdominal wound was then closed by layer sutures. The patient rallied quickly from the operation and made a rapid and uninterrupted recovery, the wound healing by primary union. In this case we had to deal with both a rupture of the liver and of the spleen and also probably of the kidney.

Case II.—Male, forty-four years of age, car-coupler, on June 16, 1897, was caught between two cars while at his work. He was brought to the Norwegian Hospital about three-quarters of an hour after the injury. On admission he was suffering much shock and showed signs of internal hemorrhage. Immediate operation was

[1] Read at the annual meeting of the Medical Society of the State of New York, Albany, N. Y., February 1, 1900.

proposed, and refused by patient, as he had had a similar injury a year before and recovered without any intervention. His condition slowly but continually grew worse in spite of vigorous stimulation, and twelve hours later he consented to operation. After proper preparations a median incision was made and on opening the abdomen there was a profuse discharge of fluid blood, between two and three quarts; the liver was immediately sought and on its under surface was found a rent an inch and a half in length and two inches deep. From the surface was a steady but moderate flow of blood. Pressure by means of a gauze tampon held in place for five minutes completely checked the bleeding. Two fine catgut sutures were then introduced and the liver wound closed. Thorough toilet of the peritoneal cavity was made and then the abdominal incision closed by layer sutures. At the close of the operation the patient was in very weak condition, but under stimulation of strychnine and whiskey, hypodermatically given, and coffee enemata, a rapid response was obtained. His recovery was rapid and uninterrupted, the patient being discharged from the hospital at the end of the third week.

The question of when to operate in these cases is the all important one and must be decided for each case individually. In the first case reported had operation been immediately resorted to I have no doubt a fatal issue would have resulted, while in the second case the delay made necessary by the patient's refusal of operation nearly cost him his life.

73 Eighth Avenue.

REPORT OF BACTERIOLOGICAL INVESTIGATIONS UPON YELLOW FEVER.

BY ARISTIDES AGRAMONTE, M.D.,
ACTING ASSISTANT SURGEON U. S. ARMY.

(Continued from p. 212.)

Experiments with Heart-Blood in Attempts at Infection.

THESE experiments could not have been undertaken at Santiago de Cuba, for obvious reasons. The method employed was to draw blood in large sterile Sternberg bulbs from the heart cavities of individuals dead of yellow fever; this blood was as soon as possible (within one or two hours) injected into the peritoneal cavity or subcutaneously, macerating the clot if necessary. Usually only blood serum was obtained from the heart.

September 18, 1899.—Guinea-pig No. 30; weight 300 grms.; given intraperitoneal injection of 3 c.c. of bloody serum from the heart of autopsy No. 18 one hour after the autopsy (eleven hours after death). It recovered.

September 18, 1899.—Rabbit No. 35; weight 1020 grms.; subcutaneous injection of 3 c.c. of bloody serum from autopsy No. 18. September 20th. It has developed a large abscess at the seat of inoculation; weight 996 grms.

September 22d.—Abscess ruptured; discharge of bloody pus; weight 990 grms.

September 24th.—Abscess cavity is closing; weight 998 grms. This rabbit finally recovered. Aside from the loss in weight and the presence of the abscess, he showed no sign of sickness after the second day.

October 27, 1899.—Guinea-pig No. 34; weight 430 grms; subcutaneous injection of 2 c.c. of bloody serum from heart of autopsy No. 21, a half hour after autopsy (thirteen hours after death). October 28th.—Apparently very sick; weight 426 grms. October 29th.—Abscess at point of inoculation. October 31st.—Died during the night. Cultures from organs gave negative results as far as bacillus icteroides is concerned.

October 27, 1899.—Guinea-pig No. 36; weight 620 grms. Intraperitoneal injection of 3 c.c. of bloody serum from the heart of autopsy No. 21. October 28th.—Is very sick; weight 612 grms. October 29th.—Has eaten some food; locomotion is impaired. It finally recovered with a contracted hind leg.

October 27, 1899.—Rabbit No. 37; weight 1086 grms.; intravenous injection of 1 c.c. of bloody serum from the heart of autopsy No. 21. October 30th.—It has been sick for the last three days, but is better to-day. It finally recovered.

November 12, 1899.—Guinea-pig No. 38; weight 380 grms; intraperitoneal injection of 3 c.c. of bloody serum from the heart of autopsy No. 23 a half hour after autopsy (thirteen hours after death). November 13th.—Apparently sick. November 14th.—It is more lively. Finally recovered.

November 12, 1899.—Guinea-pig No. 39; weight 437 grms; subcutaneous injection of 1 c.c. of bloody serum from the heart of autopsy No. 23. November 16th.—An abscess has developed which contracts the hind leg on the side of the inoculation. It finally got well, with a permanently contracted leg.

November 12, 1899.—Rabbit No. 40; weight 1072 grms; intravenous injection of 2 c.c. of bloody serum from the heart of autopsy No. 23. November 13th.—Died during the night. Cultures from the liver, kidney, bile and urine remained sterile; cultures from the spleen and heart-blood gave three organisms: a staphylococcus and two colon bacilli, one of which is pathogenic, the other not. The pathogenic bacillus produces death in guinea-pigs in doses of from 3 c.c. to 4 c.c., intraperitoneally, subcutaneously it forms abscess. Bacillus icteroides was not present.

It has not been possible to produce any disease even remotely similar to yellow fever by the experiments above outlined. In fatal cases the lesions were either purely local or the result of septicemia.

Agglutination Tests.

The efforts to ascertain the "clumping" power of yellow fever serum were directed principally against bacillus icteroides.

The results have been as expected, regularly

negative, whenever the degree of dilution and time limit were taken into consideration. In all, fifty-four tests were made with blood taken from the ear-lobe. (See table IV.)

The accompanying table will show at a glance the fact that bacillus icteroides is not distinctly affected by the action of yellow fever serum. In the two instances, with the blood of Jas. M. Hays

and S. Fichmann, the bacilli were certainly arrested in their motility and a positive reaction seemed about to take place, but repeated experiments failed to confirm this. The case of Hays is of some interest from the fact that bacillus icteroides was isolated after death.

Bacillus icteroides can be said to be agglutinated in the proper dilution and time limit only by the serum of animals infected with itself (B. icteroides) and by the serum of hog-cholera, evidently its own nearest kin. If time limit is of no account when dealing with this organism, as it might be inferred from reading Drs. Wasdin and Geddings' report, in which they state having waited three hours for a reaction (pp. 15 and 79), then we find that bacillus icteroides is agglutinated or its motility arrested by the serum not only of yellow fever cases, occasionally, but also of healthy individuals, non-immunes, as well as by that of typhoid fever and other patients and by the normal serum of some of the lower animals.

Immunizing Power of Yellow-Fever Convalescent's Serum against the Bacillus Icteroides of Sanarelli.

The serum obtained from convalescent yellow fever patients has no protective power against bacillus icteroides injected in the doses ordinarily employed with the known antitoxic serum of other micro-organisms.

Before arriving at this conclusion a number of experiments were made, as follows:

June 5, 1899.—Guinea-pig No. 12; weight 320 grms; subcutaneous injection 0.3 c.c. of a 24-hour bouillon culture bacillus icteroides (control). Died in 30 hours; bacillus icteroides recovered from blood and viscera.

Guinea-pig No. 13; 300 grms; subcutaneous injection 0.3 c.c. same culture as above, also 2 c.c. of blood serum from Pascual Rodriguez. (This serum slightly arrested the motility of bacillus icteroides.) Died in the night of June 6th. Bacillus icteroides recovered from the blood and viscera.

Guinea-pig No. 14; weight 325 grms; subcutaneous injection 0.4 c.c. came culture as above, also 2 c.c. blood serum from Pascual Rodriguez. Died in 3 days; bacillus icteroides recovered.

June 9, 1899.—Dog No. 15; weight 8½ lbs; intravenous injection 15 c.c. of serum from Pascual Rodriguez and through the same needle; 15 minutes afterwards 5 c.c. of a 24-hour bouillon culture bacillus icteroides isolated from Patrick Smith. He developed fever, vomiting and diarrhea, which lasted five days. The animal died June 14th. Bacillus icteroides was recovered from the viscera and heart-blood.

September 14, 1899.—Guinea-pig No. 26; weight 460 grms; subcutaneous injection 0.5 c.c. of a 24-hour bouillon culture bacillus icteroides (control). Died September 10th, P.M.; bacillus icteroides recovered.

Guinea-pig No. 27; weight 626 grms; subcutaneous injection 0.5 c.c. of same culture as above, also 3 c.c. of serum from Ed. Vragel. Found dead September 16th; bacillus icteroides in abundance recovered from the blood and viscera.

Guinea-pig No. 28; weight 324 grms.; subcutaneous injection 0.5 c.c. of same culture as above, also an intraperitoneal injection of 4 c.c.

of blood serum from Ed. Vragel. Died September 16th, A. M.; bacillus icteroides recovered.

Rabbit No. 29; weight 1066 grms.; subcutaneous injection of 1 c.c. of same culture as above, also an intravenous injection of 4 c.c. of serum from Ed. Vragel. Died September 18th; bacillus icteroides recovered.

October 23, 1899.—Guinea-pig No. 31; weight 620 grms.; subcutaneous injection of 0.8 c.c. 24-hour bouillon culture bacillus icteroides (to test its virulence). Died October 25th and bacillus icteroides was recovered.

Dog No. 32, weight 12 lbs.; given an intravenous injection of 15 c.c. of blood serum from Henri Duverrier. A half-hour afterwards, a second intravenous injection of 6 c.c. of same culture used on guinea-pig No. 31. The animal was sick for five days and died in convulsions October 28th. The viscera were much congested, the liver showed fatty changes and there were small subpleural hemorrhages. Bacillus icteroides was recovered from the blood and viscera. From the early experiments we were led to hope that if not decidedly protective, at least the serum of immune individuals might enable us to prolong the life of infected animals; the subsequent results, however, soon undeceived us and we plainly saw that it exerted no greater influence than would the injection of any other serum under the same circumstances.

The Serum of Convalescent Yellow-Fever Patients.

The writer firmly believes in the bacterial origin of yellow fever. Having met with general disappointment in the search for the real organism and completely lost faith in the specificity of bacillus icteroides, he desired to undertake a series of experiments to determine what curative power, if any, existed in the blood serum obtained from men who lately had the disease. It was logical to believe that the immunity conferred upon these individuals must be due to the formation of some antitoxic principle, and it was also logical to think that this antitoxin might after careful study and experimentation be of incalculable value, not only as a therapeutic means in properly selected cases, but more so as a prophylactic by its injection into non-immune subjects, in doses to be determined. But it was necessary to seek for evidence that would tend to corroborate this theory and with that purpose in view we wrote you from Santiago on July 9, 1899, as follows: "Is there any danger in injecting the serum of these recent immunes into yellow-fever patients, in an attempt to counteract the action of the yellow fever toxin, especially if care is taken in obtaining the blood from men who are otherwise well? I mean without syphilitic or tubercular taint.

"In view of the apparent slight risk, if any, and the great benefit that would be derived therefrom if successful, I think a trial would be warranted. The more I have thought upon this the more I am inclined in its favor; I am well aware of the fact that such experiment would perhaps be unprecedented, but that alone would not deter me from undertaking it But I may have considered this subject from an erroneous standpoint; if that is the case, I would like to have you point out my error to me, and it is needless to say that I shall profit by your advice and certainly desist from further consideration of the matter."

We were honored by your approval and the consent to undertake the experimental injections. Your letter reached us too late to enable us to do anything in Santiago, but upon our return to Havana we began to work in this direction.

The serum was obtained of convalescents from uncomplicated yellow fever; a careful scrutiny of their previous history was made so as to avoid bleeding men who had any syphilitic or tubercular antecedents; we also refused blood from individuals subject to rheumatic, gouty or any other diathesis or from men addicted to alcoholic drinks. This necessitated the discarding of numerous cases so that the serum collected was less in quantity than it would have been under different conditions. The fact was that we desired to surround these injections by such safeguards as might do away with such criticisms as the work, heretofore unprecedented, would call forth from those who never had the courage to put it into practise if they ever did have the conviction of the rationale of the subject.

The method employed in obtaining the serum was as follows: A convalescent was selected who had sufficiently recovered to afford the slight loss of blood (about one week or ten days after entering into convalescence). The right arm up to the shoulder was thoroughly scrubbed with soap and water, then with a solution of bichloride of mercury (1-1000) and, finally, with ether and sterile cotton, particularly around the elbow-joint; a bandage was placed about the upper arm sufficiently tight to interrupt the venous circulation; a puncture was made with a lancet into one of the engorged superficial veins, and the blood stream was received into a sterile, cylindrical glass graduate. If the flow of blood tended to diminish, the man was instructed to forcibly open and close his hands several times, when the flow would quickly be re-established. After 24 hours in an ice-chest at about 20° C., the supernatant serum is syphoned from the glass cylinder into a conical Pasteur flask, where it is decanted, so as to later secure the serum as free from red corpuscles as possible. It is unnecessary to detail here the antiseptic precautions by which the entire process was surrounded. From 120 c.c. to 300 c.c. have been drawn at a sitting and no convalescent has been subjected to more than one bleeding. At no time have we met with any difficulty in obtaining consent to be bled, nor have any untoward symptoms resulted from the amount of blood drawn.

If opportunity is afforded for the continuance of these experiments (and we earnestly hope that it will be) we think that the beneficial results

might be aided, in the presence of an epidemic, by the use of a centrifugal machine that will do away with the time necessary for the natural separation of the clot and serum. At the same time the serum will be carried from the immune to the patient within ten minutes of time, the latter receiving the leucocytes in a live state which, if they exert any influence upon the protective principle, as we believe they do, will certainly increase the therapeutic value of the injections. By the use of such apparatus a large quantity of serum will be obtained, requiring that a very small quantity of blood be taken at a sitting and thus allowing the employment of other methods than the old-time bleeding for its obtainment.

The number of convalescents subjected to this operation was as follows:

June 4, 1899.—Pascual Rodriguez, civilian, about forty years of age; in the third week of convalescence. From a vein at the elbow 184 c.c. of blood were drawn; it yielded 53 c.c. clear serum.

September 26, 1899.—Chas. Allison, civilian, thirty-one years. The day before his discharge from the hospital, 250 c.c. of blood were obtained from a vein at the elbow; it yielded 67 c.c. of clear serum.

September 10, 1899.—Ed. Vragel, private, I, 2nd Artillery, nineteen years. Two days before his discharge from the hospital we obtained 120 c.c. of blood form a vein at the elbow, which yielded 20 c.c. of clear serum.

September 16, 1899.—Chas. Mitchell, Corp., B, 2nd Artillery, thirty years. Two days before his discharge from the hospital we obtained 230 c.c. of blood from a vein at the elbow; it yielded 60 c.c. of clear serum.

September 17, 1899.—Stanley Embick, 2nd Lieut., B, 2nd Artillery, twenty-three years. Three days before his discharge we obtained 250 c.c. of blood from a vein at the elbow, which yielded 65 c.c. of serum.

September 19, 1899.—Earnest Bubeck, private, K, 2nd Artillery, twenty-three years. The day before his discharge 300 c.c. of blood were drawn from a vein at the elbow; it yielded 85 c.c. of serum, most of which became contaminated in manipulation.

October 22, 1899.—Henri Duverrier, civilian, twenty-two years. The day before his discharge from the hospital (Los Angeles) we obtained 200 c.c. of blood from a vein at the elbow; it yielded about 55 c.c. of serum.

October 23, 1899.—Wm. Stokes, civilian, twenty-three years. Four days before his discharge we drew 300 c.c. of blood from the arm, which yielded 64 c.c. clear serum.

October 31, 1899.—Peter Peterson, civilian, twenty years. The day before his discharge we obtained 200 c.c. of blood from a vein at the elbow; it yielded 40 c.c. of clear serum.

November 24, 1899.—J. O. La Fontissee, civilian, twenty-seven years. One week after his discharge from the hospital we obtained 250 c.c. of blood from a vein at the elbow, which yielded 55 c.c. of clear serum.

Some of the serum here recorded was used in experiments, as detailed in a previous chapter and a good quantity was set aside as being slightly cloudy or too highly tinged with dissolved hemoglobine, so that a comparatively small amount was employed in the following cases:

Case I.—James Gavin, civilian, seaman, forty-one years of age, admitted to hospital in the afternoon of October 11th, 1899. The patient says he has never been sick since fifteen years ago, when he had rheumatism. His habits are bad, and he confesses to being an habitual drunkard. He has lived one month in Havana. On the 9th at midnight he experienced a slight chill, severe frontal headache, rachialgia and myalgia. On the 10th, he felt better, but on the 11th became worse again and vomited everything he took; he was then sent to the hospital, where he was placed in the "suspect ward." Oct. 12.—The diagnosis of yellow fever is made. The patient's condition is made worse by the severe gastric irritation, which induces almost constant vomiting and retching. At 2 P. M. he is given an injection of 18 c.c. of serum (marked Embick, 9-18-99) under the skin of the outer aspect of the left thigh, his temperature being 103° F.; pulse, 58; respiration, 22. The urine contains about 6 per cent. of albumin. Oct. 13th, A. M.—All night the temperature has ranged around 104°. At 9:15, temperature, 102.8°; pulse, 68. "Did not like to ask nurse for urinal," so he had passed urine in bed. The lithia water that was given caused him to vomit three times, gastric juice and mucus only; complains of constant "water-brash" and "heart-burn." Urine contains about 20 per cent. of albumin (a rough estimate of moist albumin). Oct. 13th, P. M.—The gastric irritation continues. The patient retained a small quantity of malted milk; he vomits only gastric juice and mucus. At 2 P.M. temperature, 103° F.; pulse, 70; respiration, 22. A second injection is given on the other thigh, 18 c.c. serum (marked Mitchell, 9-18-99). Oct. 14th, A.M.—There was no reaction after yesterday's injection. The temperature has gradually come down to 100.4° F.; pulse, 68; respiration, 16. In spite of the uncontrollable nausea and frequent vomiting there has been nothing like "black vomit." Not even the so-called "fly-wing" specks have appeared in the acid mucus thrown up. The prostration is great, but the headache has been relieved. I ordered five grains of bicarbonate of soda every three hours in an effort to relieve the gastric hyperacidity. A remarkable feature in the clinical picture which this case presents is the entire absence of hemorrhagic tendency from any of the mucous membranes, so that we have a typical case of yellow fever infection without the bleeding from gums, mouth, stomach, intestines or into the skin. The icterus is present, well marked in skin and sclerotics, also the non-correlation of temperature and pulse and the albumin in the urine. There is a slight puffiness of the gums but no more than he had on admission. Aside

from this absence of hemorrhage, the fact that the man's mind is unusually clear and that the pulse and temperature show an inclination to come nearer together, makes me consider the patient's condition very critical. Oct. 15, A.M.—The temperature has now come down to 100° F.; pulse, 70. The patient, although extremely prostrated by the continuous retching, is perfectly lucid in mind; he asks for the bed-pan when in need of it, and complains of nothing but weakness. There is no headache; the amount of urine passed in the last twenty-four hours is 1000 c.c. Oct. 15th, P.M.—The nausea continues without actual vomiting, but even a question as to the condition of his stomach causes him to retch; the thermometer introduced into his mouth induces retching. The pulse is so thin and compressible that I decide to give one-sixtieth of a grain of strychnine hypodermically. Although all the signs of yellow fever infection have subsided I fear to lose the patient through cardiac failure. With the same purpose in mind, stimulation, he is given a third injection of convalescent's serum, 20 c.c. (marked Mitchell, 9-18-99). The temperature at this time is 100.8° F.; pulse, 80; respiration, 20. Oct. 16th, A.M.—The patient passed a rather comfortable night, although the gastric irritation, less intense, continues. From 4:30 P.M. yesterday to 9 o'clock this morning the patient has voided 280 c.c. of urine, containing about 10 per cent. of albumin. He sleeps a great deal. Temperature, 97.8° F.; pulse, 68; respiration, 20. Oct. 16th, P.M.—The man says he only feels weak, and begs to be disturbed less and permitted to sleep longer intervals. His request is granted. His mind is perfectly clear, and the efforts at vomiting occur less frequently. Oct. 17, A.M.—During the last twenty-four hours the patient has passed 2013 c.c. of urine; it contains about 10 per cent. of albumin. There has been no vomiting since last night. Patient says he is hungry. Temperature, normal; pulse, 68. Small quantities of beef extract are allowed. Nothing in the way of medication except the strychnine has been given in this case, and we believe that the first two injections of serum were sufficient to counteract the yellow fever toxins; there was no indication for the third injection except the exhaustion due to the accidental presence of the gastritis, and it was administered as a tonic only. Oct. 18th, A.M.—The patient continues to do well, is still hungry, and has no more gastric disturbance. Has passed 1945 c.c. of urine during the last twenty-four hours. Albumin about 3 per cent. less than at any time during his illness. He made a rapid convalescence.

Case II.—A. D., thirty years of age, a cattle-dealer. He arrived in Havana two months ago. On the 15th of October at about 4 P.M. he felt chilly after a shower-bath and lay down to sleep. At about 7 P.M. he awoke with general malaise. During the following night he had a severe headache; next morning felt feverish, rachialgia and nausea. A physician was called, who prescribed a calomel purge followed by a dose of magnesia. We saw the case the following morning. Oct. 17, 1899, A.M.—Temperature, 102.2° F.; pulse, 74; respiration, 22. The face is much flushed, also the neck and chest, with some capillary stagnation. He says that he feels well, except for "that pain in the back." The conjunctivæ and gums are much congested; the latter are swollen, the tongue slightly furred and dry, the papillæ enlarged, the border indented by the teeth. The epigastric tenderness is marked; there is some constant and distressing nausea, but no vomiting. The spleen is enlarged, also the liver; neither one is tender to pressure; the patient says that he suffered repeatedly from attacks of malaria in Missouri, about two years ago. He never had rheumatism, but had gonorrhea up to one month ago. He does not drink to excess. Diagnosis of yellow fever seems clear. He lives at home and is properly isolated. Oct. 17th, P.M.—Temperature, 100.4° F.; pulse, 70; respiration, 22. He feels well enough to get up, except for some slight headache. This morning's urine contains 0.50 grm. of albumin per liter (Esbach's albuminometer), also pus-cells and epithelium. The patient is given a subcutaneous injection of 20 c.c. of serum (marked Bubeck, 9-19-99) at the outer aspect of the left thigh. He is allowed to drink Apollinaris water and lemonade. Oct. 18th, A.M.—Temperature rose at 9 P.M. to 102.4°; pulse, 72; respiration, 24. At 10 P.M. it was necessary to draw 300 c.c. of urine by catheter. Soon after he vomited a small amount of clear gastric juice. Temperature, 101.2° F.; pulse, 70; respiration, 20. He complains of a gnawing sensation at the stomach, but has no nausea; there is tenderness on slight pressure. At 6 P.M. he voided 250 c.c. of urine containing 1 grm. of albumin per liter (Esbach's albuminometer), also epithelial bladder and kidney cells. Oct. 19th, P.M.—It was impossible to see the patient this morning. The temperature was down to 100° F.; pulse, 68; respiration, 20; but at present it is 101.4°; pulse, 70; respiration, 22. The gums are puffy and ready to bleed if pressed upon. Vomited clear mucus during the night; he seems much prostrated. The stools have been yellow; the enemata have brought forth only mucus or yellow feces. During the last twenty-four hours he has passed 1268 c.c. of albuminous urine, 0.50 grm. of albumin to the liter (Esbach's); also some bladder epithelium and hyaline casts. At 4 P.M. he is given a second injection of convalescent's serum (marked Bubeck, 9-19-99) 20 c.c. under the skin of the other thigh. Oct. 20th, A.M.—The patient passed a comfortable night. At 8 P.M. last night the temperature was 100.6° F.; pulse, 66; respiration, 20. Through a slight misunderstanding, the attending physician ordered some broth given, which was immediately vomited; at 8 P.M. the patient's general condition is much improved; his eyes are tinted yellow, the skin slightly so. There is no pain or tenderness at the site of the injections. There was no reaction after yesterday's injection. There is barely any epigastric

tenderness. Patient would like to have some food. Oct. 21st, A.M.—Patient sitting up in bed. Says he is hungry. The sclerotics and skin are very yellow. Temperature, 99° F.; pulse, 64; respiration, 18. He says that he is very weak, but asked his nurse to sit up, because "his bones ached from lying in bed." The patient is evidently entering into convalescence at the sixth day after invasion. The urine still contains albumin in small quantity. The absence of any hemorrhage is remarkable, and considering the severity of the initial symptoms it can only be attributed to the antitoxic effects of the serum. This man made an uninterrupted recovery.

Case III.—B. F. Markwood, about twenty-four years old, admitted Oct. 24, 1899. The patient was taken sick with nausea and vomiting on Oct. 22d. He lived in the same tent at Cabañas Fortress with a man who developed yellow fever at the same time, and died of it; he had also been exposed to infection from a case in the same camp a week before. He had been ill two days before he began to vomit, with headache and "bone-aches." He has vomited "brown stuff" twice. Says he does not drink to excess. He never had venereal disease nor malaria or rheumatism, but had scarlet fever when a boy. Oct. 24th, P.M.—On admission, temperature, 103° F.; pulse, 74; respiration, 20. He complains of a gnawing at the stomach, headache, and rachialgia. There is some bleeding from the mouth, the gums and conjunctivæ are very congested, the latter have a distinct yellowish tint. There is capillary stagnation at the neck and chest. He is given 20 c.c. of serum (marked Stokes, 10-23-99), under the skin of left thigh. Albumin in urine on admission, 1 grm. per liter (Esbach's). Looks like a case in the fourth or fifth day after invasion. Oct. 25th, A.M.—After yesterday's injection the temperature rose to 103.6° F.; pulse, 74; respiration, 24. During the night it ranged around 102.6° F. At present, temperature, 102.4° F.; pulse, 78; respiration, 25. At 1:20 A.M. he had a "black vomit" and some hemorrhage from the gums; at 3:40 A.M. he again vomited a quantity of mucus with some "fly-wing" specks. The gums do not bleed at present. He complains of epigastric pain and headache which "comes and goes" at times. Oct. 25th, P.M.—The hemorrhages have ceased. Temperature, 103.6° F.; pulse, 76; respiration, 24. The pulse is full and compressible. There is great depression. He is given a second injection of 20 c.c. serum (marked Duverrier, 10-22-99). Has passed 868 c.c. of urine during the twenty-four hours; it contains 1 grm. per liter (Esbach) red blood-corpuscles, granular and epithelial casts in quantity. Oct. 26th, A. M.—The patient spent a rather comfortable night. The injection yesterday produced no reaction. The temperature from 103° came down to 102° three hours afterward; at present temperature, 102.8° F.; pulse, 87; respiration, 23. Has not vomited during the last twenty-four hours. His expectoration is streaked with blood; the gums bleed slightly. He complains of feeling hungry. He is allowed 25 c.c. malted mik every three hours. Oct. 26th, P.M.—The patient vomited the malted milk, which was immediately discontinued; he complains again of nausea and gastric distress. Temperature, 103° F.; pulse, 80; respiration, 26. Petechial spots have appeared over the arms and chest. He is allowed to drink lemonade and lithia water. He has passed 1990 c.c. of urine in twenty-four hours. It contains 1.50 grm. albumin to a liter (Esbach), numerous renal cells in fatty degeneration, granular and epithelial casts, some pavement epithelium and many fat globules. Oct. 27th, A.M.—The patient is very thirsty and complains much of abdominal pain. It was necessary to draw 120 c.c. by catheter last night. Temperature, 98.8° F.; pulse, 99; respiration, 30. There is great prostration and the numerous purpural spots are ominous of a fatal termination. Oct. 27th, P.M.—At 2:15 P.M. the temperature was 98.8° F.; pulse, 98; respiration, 38. There have occurred two "black-vomits." Enemata bring out tarry particles. There is great pain and marked kidney impairment. Warm baths, dry cupping, etc., have not seemed to affect the elimination. He has passed but 360 c.c. of urine in twenty-four hours; it contained albumin, 1.50 grms. per liter (Esbach), numerous red blood-corpuscles, free fat globules, renal and ureter epithelium, granular and epithelial casts. Oct. 28th.—The man died at 2:05 A.M. after a vomiting spell. It was after much questioning of the patient and his friends that we confirmed the suspicion that when admitted to the hospital on Oct. 24th, he was in the fifth day of his disease, or else we would never have injected him with serum, for we know that cases admitted at this stage of the infection usually terminate fatally.

Case IV.—John W. Buckman, twenty-eight years of age, sailor, admitted Oct. 26th. The patient has been living at Cabañas Hill with carpenters at work on the fortress. He was taken sick on the 25th, when he felt ill and his head began to ache; pains in the back and legs came afterward. Vomited at 3 in the morning, subsequently feeling much better. He is a constant drinker. Oct. 26th, P.M.—The patient complains of chilly sensations, the face is flushed, eyes injected, gums swollen, tongue badly coated, and breath offensive. His pulse is full and regular. He has a dull expression, is blue-eyed and fair-skinned. Temperature, 103° F.; pulse, 86; respiration, 20. We gave him 15 c.c. of convalescent's serum (marked Duverrier, 10-22-99). Oct. 27, A.M.—At 10 P.M. last night it was necessary to draw 770 c.c. of urine by catheter; it contained traces of albumin, fat globules, a few pavement epithelia. Temperature, 101.2° F.; pulse, 76; respiration, 22. Oct. 27th, P.M.—The patient was again catheterized and 475 c.c. of urine withdrawn. He is resting quietly and says he feels comfortable. The heart action is good. Temperature, 102.2° F.; pulse, 84; respiration, 27. The face and neck are very much congested.

We gave him 15 c.c. of serum (marked Duverrier, 10-22-99). Oct. 28th, A.M.—Temperature, 100.8° F.; pulse, 74; respiration, 22. He has voided 525 c.c. of urine this morning and feels otherwise well except for a slight gastric tenderness. Oct. 28th, P.M.—The patient complains of nothing but slight gastric pain He has slept a good part of the day. The urine contains 0.25 grm. of albumin per liter (Esbach's albuminometer), a few epithelial cells and mucus. Oct. 29th, A.M.—The patient says he is hungry this morning. Temperature, 99° F.; pulse, 54; respiration, 20. He complains of some pain in the bones, probably from the prolonged recumbent position. Has passed 1870 c.c. of urine during the last twenty-four hours, containing 0.20 grm. per liter of albumin (Esbach's) and some mucus. Oct. 30th, A.M.—Complains that the beef extract does not agree with his stomach; desires malted milk. The enemata produce pain in the anus; they are discontinued. Temperature, 99.2° F.; pulse, 64; respiration, 20. Has passed 1760 c.c. of albuminous urine during the last twenty-four hours, 0.25 grm. of albumin per liter (Esbach's). Oct. 30, P.M.—The patient has continued to improve; his gastric tenderness has left him. Temperature, 99.2° F.; pulse, 54; respiration, 20. Oct. 31st, A.M.—Our patient spent a very quiet and comfortable night. The pulse, although very slow, is full and regular. He has voided 1465 c.c. of urine in twenty-four hours. It contains a trace of albumin and mucus. Temperature, 98.8° F.; pulse, 50; respiration, 20. This man made a rapid and uninterrupted recovery.

He received but 30 c.c. of convalescent's serum in two injections, one on the second, and another on the third day of his illness. The temperature began to subside after the second injection, and he was practically convalescing on the fifth day after invasion. The onset was severe and the initial symptoms promised a serious case; the fact of his being a "constant drinker" decidedly pointed against a cheerful prognosis There has been no hemorrhagic tendency. The gums became puffy and congested, but never bled; the patient has not vomited at all during his confinement at the hospital in spite of the gastric irritation and the fact that we allowed small quantities of nourishment at stated intervals throughout. Absolutely no other treatment but that outlined here was employed.

Case V.—Guillermo Hernandez, twenty-six years of age, Spanish peddler; has been about ten years in the island, always living in the country, coming to town only for the purpose of buying merchandise. Lately he has resided in the city for about ten days. He has never been sick except with malarial fever, of which he has been suffering for one or two years. Admitted as suspicious yellow fever on Nov. 14, 1899. On Nov. 12th, in the afternoon, he felt chilly and thought he was going to have one of his usual malarial attacks; fever soon followed and then pains over all muscles, bones and small of the back, such as he had not felt with other malarial paroxysms. He has not vomited, but is a little nauseated. Nov. 15th, A.M.—The patient is resting quietly. Temperature, 100.6° F.; pulse, 88; respiration, 28. Complains of body-pains, headache and general malaise; also some colic the result probably of a cathartic that was administered this morning. The patient is dark-skinned with dark hair and eyes. There is some capillary stagnation; a flush, more perceptible on pressure, extends over the face, neck and chest. Slight epigastric tenderness. Eyes congested and the sclerotics stained yellow. The tongue is furred, moist, indented at the edge by the teeth. The gums are congested. The urine contains 0.10 grm. of albumin to the liter (Esbach's albuminometer). He is given subcutaneous injections of convalescent's serum, 35 c.c. in two doses (marked Peterson, 10-31-99). Nov. 15th, P.M.—The temperature has suddenly risen to 105° F.; pulse, 120; respiration, 30. The patient complains of great thirst and of pain in the whole body. Of course it is at once suspected that the man really has malaria and not yellow fever; but the writer is of the opinion that we have to deal with a case of double infection, such as he observed at Santiago, and six of which he has lately reported before the "Societad de Estudios Clinicos" of Havana (*Progreso Medico*, October, 1899). Nov. 16th, A.M.—As expected, the temperature came down during the night to 97°, and it was necessary to administer a small dose of brandy. At present he feels better. Temperature, 100° F.; pulse, 76; respiration, 24. During the last twenty-four hours he has passed 1200 c.c. of urine; it contains 0.25 grm. of albumin per liter (Esbach's), granular and epithelial casts and renal epithelium. The icterus is greater than yesterday. There is slight headache. The tertian malarial parasite is found in his blood. Three grains of quinine are ordered every hour. Nov. 16th, P.M.—The patient complains of epigastric pain, headache and "backache"; there is some nausea. He has vomited twice a quantity of gastric juice and mucus, without any trace of "coffee-ground" matter. Nov. 17th, A.M.—The patient has passed 730 c.c. of urine during the last twenty-four hours, containing 0.25 grm. of albumin per liter (Esbach's albuminometer), also mucin, hyaline and granular casts. At present the temperature is 101° F.; pulse, 78; respiration, 20. The blood shows the presence of a few pigmented leucocytes but no plasmodia. The quinine is discontinued. There has been no evidence of hemorrhagic tendency in spite of the symbiosis which evidently exists in this case. The icterus is marked and the gums are puffy and ready to bleed if compressed. Nov. 17th, P.M.—The patient asks for food. Temperature, 98.8° F.; pulse, 62; respiration, 18. The tongue is coated and rather dry. Nov. 18th, A.M.—The patient has slept well during the night. Temperature, 98° F.; pulse, 52; respiration, 16. During the last twenty-four hours he has voided 1820 c.c. of urine containing 0.50 grm. of albumin per liter (Esbach's albuminometer), a few

hyaline casts and renal epithelium. Nov. 19th, A.M.—The patient continues to do well. The urine still contains a small quantity of albumin and some renal epithelium. He has passed 1220 c.c. of urine in the last twenty-four hours.

Major Ducker is of our opinion that the case was one of yellow fever infection occurring in a malarial cachectic. The high temperature with the low pulse and the marked albuminuria left no room for doubt of the yellow fever infection, while the presence of the malarial organism soon after the sudden rise of the temperature, and its disappearance upon the exhibition of quinine, bore sufficient evidence to the paludic invasion. That cases in which this symbiosis has been observed are more prone to the hemorrhagic tendency than those of a single infection has been pointed out by the writer in the article referred to; yet in this case, as in the other three here recorded, where the convalescent's serum has been administered before the fourth day of the disease, absolutely no hemorrhagic tendency has shown itself. Two things have been forcibly impressed upon us while carrying out these experimental injections; one has been sufficiently noted, *e.g.*, the absence of hemorrhagic tendency; the other is the rapidity with which patients who received the serum went through the period of convalescence; the fever having once left them, their reparative functions were quickly started and they were ready to return to their business in an unusually short period of time.

It may not be untimely to state that there were other patients than those here recorded also treated by serum injections, all of whom recovered, but we have purposely left them out, because through a misunderstanding they were given some medication or other during their illness, in addition to the convalescent's serum, and we fear that if we counted them among the cases who received nothing but serum, their recovery might be attributed to the phenacetine, or the caffeine, or the calomel, or what not, that was given them, and which certainly exerted no action upon the yellow fever toxins. That the serum of convalescents is perfectly innocuous we have demonstrated upon our own person. It is more readily absorbed than the equine serum; but it has never produced any cutaneous manifestation, and within twenty-four hours every sign of the injection has disappeared, except, of course, at the point of puncture, where a minute red spot may be visible. We know, it need not be pointed out to us, that four cases can hardly be considered as sufficient evidence upon which to base any final opinion, but it cannot be denied that the disease has been distinctly modified in every instance (not counting Case No. III, where the serum was administered by mistake at the fifth day of his illness) and we have refrained from injecting (and we shall continue upon the same course) any cases which were seen after the fourth day of the invasion.

There are numerous facts still to be ascertained with regard to this method of treating the disease, not the least important of which is the determination of the power in each individual serum and the amount required in the treatment of each case, but this can only be done after a comparatively large number of cases have been studied, which we believe will be an easy matter in the early future. The therapeutic value of these injections once established on a plain and scientific basis, their immunizing power can more easily be determined, and it is not unlikely that a much smaller quantity than that used in treatment will render the necessary protection to individuals whom we to-day consider as non-immunes. The impending and necessary foreign immigration to this island would be very greatly benefited by it.

CLINICAL MEMORANDUM.

A CASE OF POST-EPILEPTIC AMNESIA.

By DAVID TRUMBULL MARSHALL, M.D.
of New York.

The following case is reported not because of its extreme rarity, though the general practitioner is not so liable to observe the phenomena as are residents of hospitals for the insane or homes for the epileptic and feeble-minded, but because of the gradual increase of interest that is manifested, especially from a medico-legal point of view, in the protean aspects of this peculiar disease, epilepsy. The amnesic period, ten days, is not very long, yet it was of sufficient length to have allowed the patient to have committed peculiar acts or even crimes had she not been kept at home and promptly restrained by drug influences. The difficulty in obtaining a history of epilepsy was also brought out in the present instance and emphasized the necessity of searching examination, as it was only after the entire period of illness had passed that it was admitted that the patient had ever had any "twitching" movements when she had her "fainting" spells, as they were termed.

Miss B., aged twenty-two years, five feet eight inches in height; weight, 150 pounds; occupation light housework.

Family History.—Her father was a professional man, and was for years a heavy drinker. He died at the age of forty-one years, of "inflammation of the bowels."

The mother still lives, at the age of forty years. She is a healthy woman, although somewhat nervous. One sister, twenty-four years of age, has always had chorea. Two brothers, respectively seventeen and fourteen years of age, are apparently normal.

Personal History.—The patient had measles and diphtheria in infancy, scarlet fever at the age of five years. She has always been well until she began to menstruate, at the age of twelve years. At sixteen years of age the patient began to have peculiar attacks of fainting, with occasional attacks of a more general convulsive nature.

The severe attacks were never of the worst type of *grand mal*. They usually consisted of a stiffening of the limbs and muscles of the face, which lasted for one or two minutes. These attacks have persisted since the age of sixteen, coming on at intervals of one or two weeks. They are apparently more frequent at the menstrual period and after excitement or over-exertion. There was no uniformity in the mode of their onset and they were not preceded by any aura, nor for the majority of instances could a history of hebetude or sleepiness following the attack be obtained. The patient exhibited none of the numerous stigmata often associated with this condition. For a week previous to November 3, 1899, the patient had been cross and moody and suffered more or less from headache.

On October 30th, it being about the time of a menstrual period, the patient began to suffer severely from dysmenorrhea and pain in the ovarian region. On November 2d she had a fainting attack, as her mother expressed it, fell face downward on her bed, and remained motionless for several minutes. No muscular twitchings were noted by her mother. On attempting to arouse her she became violent, tore her clothing and struck at all who came near her. I first saw the patient at this juncture. She was in bed, was talking rapidly and incoherently, and attempted to tear the bed-clothing. Her own night clothing she had torn in shreds. She did not have any knowledge of her surroundings and did not recognize her mother nor sister. As she was so extremely violent, raising her voice, crying and screaming, she was given a hypodermic injection of one-half of a grain of morphine sulphate, which quieted her somewhat for a short time. This dose had to be repeated next day. On the third day she became more quiet, and one one-hundredth of a grain of hyoscine hydrobromate was substituted for the morphine. This was given by mouth two or three times a day.

After the first three days of violent behavior the patient talked and laughed with her friends, but she imagined that she was at a school where she had been when fifteen years of age, and that these friends were teachers and pupils in the school. Her mother, who was in constant attendance upon her, was thought to be the head teacher; and her brother she took to be one of the attendants in the kitchen of the boarding-school.

She had utterly forgotten every impression that she had received since she was fifteen years old. A diagnosis was made of post-epileptic furor followed by some amnesic state, although the mother and sister tried in every way possible to evade a searching history. The diagnosis was confirmed in consultation with Dr. S. E. Jelliffe, and a hopeful prognosis with reference to the immediate condition was given. On the tenth day after the beginning of the attack the patient suddenly became rational, and has remained so since. She has no recollection of any incident which occurred during her illness.

Later investigations revealed a more straightforward history of epilepsy than could be obtained at the time, as it was the desire of the family to keep all knowledge of the facts of her previous attacks from every one in order that matrimonial prospects might not be blighted.

205 West 106th street.

MEDICAL PROGRESS.

Treatment of Aortic Aneurism.—The recently recommended gelatin-injection treatment is the subject of an article by N. Kalendern (*Klin. therap. Woch.*, Jan. 28, 1900). The first indication to be met in curing aneurism sacs is to eradicate as much as possible the cause. Syphilis being the most common etiological factor, an antiluetic treatment would seem in place were it not for the fact that in the majority of cases the media is too much destroyed to admit of good results. By increasing the coagulability of the blood the sac may, however, be obliterated, and this is most efficiently accomplished by the use of gelatin. As an example, the case of a patient with aneurism of the transverse arch is cited, in which paralysis of the recurrent nerve was the prominent feature. Although of undoubted syphilitic origin the iodides aggravated the condition. Gelatin injections (1 gm. gelatin in 100 c.c. sodium chloride solution once a week) were then resorted to, with the remarkable results that after five weeks the patient was practically free from symptoms both subjective and objective.

Crurin in Ulcers.—Crurin (chinolin bismuth rhodonate) forms a coarse, yellowish-red powder of strong odor and insoluble in the usual media. It is disinfectant and furthermore forms a scab on ulcers and leads to active granulation and rapid healing. K. Steiner (*Therap. Monatshft.*, Jan., 1900) is well pleased with the results he has obtained in ulcers of the leg and finds that even in chronic cases with much induration, a healthy reaction is incited if moist applications of Burrow's solution are used for some time before applying crurin. It is generally best to use it pure unless the raw surface is extensive, when it may be diluted with starch. Following the application some smarting usually occurs, but this is of transient character. A cure is generally affected in from two to six weeks, and this method of treatment should be given a fair trial before surgical intervention.

Largin for the Eye.—Marczel Falta reports (*Wiener klin. Rundschau*, Jan. 21, 1900) on the newest of the silver preparations, namely largin. Heretofore, protargol possesed marked superiority over its fellows, both in the percentage of silver and in its general therapeutic properties. Largin, however, has superseded it inasmuch as it contains fully 11 per cent. of silver, whereas protargol has but 8 per cent. Not only in this re-

spect does largin merit consideration, but it also far exceeds protargol (Pezzoli) in its germicidal powers. Indeed, even the nitrate of silver suffers in comparison with this preparation. A solution of 1-4000 of largin will kill the gonococci of a pure culture in ten minutes, while neither silver nitrate 1-2000 nor protargol will accomplish this. Pezzoli has demonstrated that none of the other silver compounds has such a power of penetration as has largin. The power of the tissues to take up this drug is one of the chief reasons for its successful use, especially in cases of conjunctivitis and diseases of the lachrymal ducts. The eye can readily bear a solution of 10 per cent. strength although a slight inflammation, evidenced by reddening and a little pain, is caused thereby. Instillations of largin several times daily are recommended in severe conjunctival affections with large amounts of secretion. The secretion rapidly diminishes in amount and a return to the normal condition follows. In cases in which both protargol and largin have been used, the author prefers and recommends the latter. The only drawback is a slight inflammation following its use. This is caused by its alkalinity, which, instead of being baneful, is in reality of great use to the drug in its therapeutic application.

Ichthyol in Joint Affections.—Stimulated by the good results following the use of ichthyol in chronic rheumatism, G. Edlefsen (*Therap. Monatshft., Jan.,* 1900) was led to try a more recent preparation, ichthyolvasogen, in this and allied conditions. The great powers of penetration possessed by this compound have proven it of especial value in the chronic monoarticular arthritis following the acute lesion and even in the polyarthritic form, and in arthritis deformans it did not disappoint. Eight to ten drops should be used for the larger joints and two for the smaller ones; when well rubbed in the good effects of massage will be added to the curative action of the drug. In conditions where much tenderness exists, however, massage is contraindicated and the usual solution of ichthyol in alcohol and ether is to be preferred.

Imperforate Rectum.—W. P. Montgomery (*Lancet,* Feb. 3, 1900), having operated on ten cases of imperforated rectum, makes these observations: In no instance did crying cause the perineum to bulge. The cases were treated by doing left inguinal colotomy, but the cecum presented three times, the sigmoid once, and, in the remainder, the small intestine. In only two cases was there distention of the lower end of the large bowel. Peritoneal repair in these small children is very slow and inefficient and, therefore, especial care should be used in the suturing at the colotomy. In two of the cases the obstruction was at the cecum, which was twisted so as to form a volvulus. From the life-saving point of view the perineal route has marked limitations. In the majority of cases the gut cannot be found; such children cannot endure prolonged operation. The acute obstruction is often at the cecum. The anus in the groin is more comfortable and easily cared for than the perineal one. The majority of children recovering from the perineal operation require constant attention to prevent stricture formation. If more than one half-inch separates the rectal pouch from the surface, a perineal anus causes constant trouble. In view of all these facts, routine colotomy is the best procedure for these patients.

Appendicitis.—J. O'Conor (*Lancet,* Feb. 3, 1900), after considerable experience with appendicitis, makes the radical statement that every case of appendicitis should be operated on as soon as diagnosticated, and gives the following reasons: No one can at the attack's onset predicate a spontaneous cure. Perforation without adhesions may suddenly occur in any case, and this complication is invariably fatal. Removal of the appendix is the most accurate method of diagnosis and cure, and the patient will never again have appendicitis. An appendix once infected is always infected and remains prone to a recurrent attack. When no actual recurrence takes place, the adhesions so frequently formed cause chronic digestive and various painful disturbances rendering life miserable. Once having entered the abdomen, never consider the operation finished until the appendix has been removed. When the abscess is simply drained, recurrent attacks are very frequent. To leave a moribund appendix in a living abdomen is not sound surgery.

Chronic Constipation in Infants.—It is an every-day observation that costiveness is more frequently seen in children brought up with artificial food than in those fed with mother's milk. H. Doerfler (*Münch. med. Woch.,* Jan. 23, 1900) ascribes this to the too great dilution in which cow's milk and other substitutes are given. A hyperemia is established in the gastro-intestinal mucosa by the fluid, which soon leads to increased absorption of water and polyuria. If this pathological condition persists it will eventually become chronic; the follicles will no longer be able to assimilate so thoroughly the solid constituents of the food, and constipation is inevitable. From the character of the feces it can be seen that the usual food is too dilute and contains too little fat and that the casein is not well digested. Hence it is advised to give cow's milk in smaller but more concentrated form, and also to add butter to the diet. This latter should be given separately and should be as fresh as possible. Children two to three months old should receive a teaspoonful morning and evening until relieved, then the same dose every second day. It is usually taken readily and not only is the indicatis morbi met, but the general health is much improved.

Plasmon as a Food.—Within the last years great efforts have been made to discover some proteid which could replace the albuminous principles of our food in disease. Such a compound

must be sufficiently cheap to make its use among the lower classes possible, and should be pleasant to take so that its continued use will not nauseate. C. Virchow (*Therap. Monatschft.,* Jan., 1900) thinks that in plasmon the ideal compound has been found. By experiments on himself the author has discovered that plasmon is perfectly digestible and, since almost all the nitrogen is used, concludes that it exceeds meat in nutritive value. It may be given as bread or in solution, but can probably be combined with many articles of food.

Iodoform in Tuberculosis.—Zera J. Lusk (*Medicine,* Feb., 1900) attributes the cure of three cases of tuberculous peritonitis to the application of an iodoform poultice from the ensiform cartilage to the pubes and on either side to the spinal column. The poultice consisted of one ounce of iodoform and six ounces of vaseline spread on cloth. He also applied such a poultice to the chest in a case of pulmonary tuberculosis, and to the knee in tuberculous synovitis. Rapid recovery took place in each instance.

Dilating Esophageal Strictures.—J. S. Pyle (*Phila. Med. Jour.,* Feb. 3, 1900) describes his apparatus for stricture dilatation. It consists of a No. 12 rubber tube having attached to its distal end a finger-shaped contrivance, consisting of external and internal tissue-rubber sacs, enclosing between them a fine silk sac to give strength. An olive-pointed piano wire guide is inserted, and the apparatus passed into the esophagus until the guide has carried the dilatable sacs partly beyond the stricture. Warm water is now forced in gradually and the stricture dilated as the sacs expand. The sacs may be in graded sizes. The operation causes little discomfort, an anesthetic is not necessary, the patient is not confined to bed, one has a perfectly controllable, evenly exerted, dilating force, and the risks involved in Abbé's operation, which necessitates gastrostomy, are avoided.

Prostitution and Venereal Disease.—Prostitution is the indiscriminate abuse or use of the sexual instinct outside of the marital relation and must apply in its broadest definition to woman and man alike. Isadore Dyer (*Phila. Med. Jour.,* Feb. 10, 1900) does not think the world manages the question of prostitution entirely right. He does not believe in restriction, as it usually makes the probability of disease greater. The tendency of womankind, in this country, to assume a place in all ranks of livelihood and life, side by side with men, is, the writer thinks, doing much to free the next generation of women from the control of man. This is being done by education, whereby all classes, ages, and men are acquiring a healthy knowledge of sexual obligations and of the conditions which are conducive to sexual abuse, and which create the morbid instinct. The strongest factor in the reform of women must be her emancipation through her raising the intellectual standard of her sex. The writer believes that prostitution can be checked and venereal diseases abated (1) by education of children before and as they become sexually mature, by teaching them physiologic, especially sexual, laws; (2) by creating a spirit of tolerance, rather than of abhorrence of fallen women in the minds of men and women, and by opening unadvertised homes where they may find opportunities of education in interesting lines and wholesome occupations; (3) by recognizing the fact that a prostitute, or sexual pervert, is a victim of civilization, and not a criminal. Various means have been taken by different countries to restrict venereal diseases, but they are not very successful. Dyer believes that all cases of gonorrhea and its acute complication, in public patients, should be confined in hospitals, and also all cases of syphilis as far as possible, during the eruptive stage or any acute manifestations of the disease. He thinks that legal restrictions should be made whereby those afflicted with syphilis and gonorrhea may be prevented from infecting others. Such a law would be difficult to enforce, but the educational effect would be good

Mixed Typhoid and Malaria.—Although the cases in which typhoid and malarial fevers simultaneously occur are frequently reported, a positive diagnosis can seldom be made and the combination of the two is probably extremely rare. The case of a soldier in the recent war in Cuba is reported by J. L. Bevans (*N. Y. Med. Jour.,* Feb. 10, 1900). A characteristic course of typhoid was run for eleven days, when quotidian chills developed and the malarial organisms were found for the first time, although previous examinations of the blood had been made. The administration of quinine stopped the chills and two days later malarial organisms could not be found. The temperature curve and symptoms of typhoid then persisted for twelve days. The Widal test proved negative each time until after the malarial attack had ceased and then a slight clumping appeared, followed in a few days by a positive Widal reaction.

Bradycardia.—Bradycardia is the name given to those cases of slow pulse—below 60—which are synchronous with the heart's systole. Richard F. Chase (*Boston Med. and Surg. Jour.,* Feb. 8, 1900) reports a case in detail and presents a table of 35 cases collected by himself under the heading of idiopathic bradycardia. This condition in his opinion is of common occurrence. Men are affected more often than women. The average age at which it occurs is about sixty. He does not agree with the classification of this disease by Riegel into physiological and pathological bradycardia, nor with any other previous classifications, but divides the cases into (1) physiological bradycardia, those cases due to physiological conditions only; (2) idiopathic bradycardia, which consists of those cases occurring in advanced life without discoverable cause; and (3) symptomatic bradycardia, to which class belong those cases in which the slow pulse is a

symptom of some usually known condition. The bradycardial symptoms consist of attacks of syncope, vertigo, dyspnea, and sensitiveness to cold. The outcome of the idiopathic cases is usually fatal. The immediate cause of bradycardia may be due to (*a*) a condition of the nerve centers producing irritation of the pneumogastric or paralysis of the sympathetic (accelerator) nerves of the heart; (*b*) a condition of the pneumogastric which increases its irritability; (*c*) a condition of the sympathetic nerves paralyzing them; or (*d*) to some condition of the cardiac ganglia in which the influence of the pneumogastric preponderates; or (*e*) to a condition of the heart muscle whereby it fails to respond to normal stimulus; or (*f*) to poisons acting on the nerve centers or endings. Not much is known of the physiology or pathology of bradycardia. In 31 autopsies, however, the following lesions were found: Disease of the brain in 6; disease or injury of cord in 8; disease of heart in 10; disease of circulatory system in 5; and no lesion in 2. The treatment should consist of the removal of the cause when it is known, and in other cases it must be symptomatic although the majority of cases show little benefit from treatment.

Albuminuria.—Formerly albumin in the urine was thought to mean Bright's disease, but it is now commonly accepted that there may be albuminuria without Bright's disease, and that the occurrence of a particular proteid in the urine carries with it a significance peculiar to itself. Thos. P. Prout (*Phila. Med. Jour.*, Feb. 10, 1900) says that no less than five proteids are found in the urine, *viz.*, (1) serumalbumin; (2) serumglobulin; (3) nucleo-albumin, or mucin; (4) peptone; (5) albumose, or propeptone. He describes these proteids and says that the first two are of special importance because of their association with nephritis. Mucin is usually present normally in small amount in the urine. Peptone and albumose should never appear in normal urine. Serumalbumin in the urine may be due to (1) renal disease, or (2) to the pressure of pus, spermatozoa, blood, or elements of tumors. Urine containing these substances will give the albumin reaction. Renal albuminuria may be divided etiologically into (1) that following certain febrile diseases; (2) nervous albuminuria, following some diseases of the central nervous system; (3) hematogenetic albuminuria; (4) toxic albuminuria; (5) albuminuria of pregnancy; (6) congestive albuminuria; (7) albuminuria due to long-continued exposure. In these conditions the amount of albumin in the urine varies according to the cause. In some there will be no albumin, or at least a mere trace, and in others it may be present in the urine at one time and absent at another. The appearance of pepton in the urine is pathologic and is of interest in certain conditions. Being an element of pus it is expected in the urine in cases of empyema, or other extensive pus-formations. The writer looks for it in (1) the ulcerative stage of typhoid fever; (2) suppurative processes; (3) pneumonia, at the crisis; (4) after childbirth, (5) in carcinomatous affections, and (6) in phosphorus poisoning. The absence of pepton from the urine does not necessarily indicate that suppurative lesion is absent, but its presence is of considerable corroborative value. Albumose is not of much importance as yet. Mucin is increased in quantity in the urine in urethritis and cystitis and is, therefore, of some diagnostic value. Prout describes six tests for finding albumin, mucin, albumose, and pepton.

Inguinal Hernia in the Young.—J. W. Seaver (*Yale Med. Jour.*, Feb., 1900) publishes a non-operative treatment of hernia in young people. It is best adapted to herniæ of moderate size and duration. After the hernia is controlled by a suitable truss, the patient twice a day goes through exercises planned to develop the muscles in the abdominal region, as well as those which deepen the chest, and thus make more room in the abdominal cavity. The exercises are gradually made more severe and complex. Under this treatment there is a natural tendency to the closure of the abnormal aperture. Local massage of the ring region starts up a cell activity that markedly strengthens the tissues. Under this treatment seventy per cent. of the cases have been freed from the necessity of wearing a support to control the hernia.

Nervous Dyspepsia.—Boardman Reed (*Internat. Med. Mag.*, Jan., 1900) considers this to be a local condition of the same type as general neurasthenia. The term should be applied only to those gastric symptoms which cannot be traced to any organic lesion or to any well-known disorder of function. Any stomach disease may be mimicked, but in nervous dyspepsia the discomfort is, as a rule, limited to the digestive period, the patient feeling well while the stomach is empty. The dyspeptic symptoms have no definite relation to the kind of food ingested, but come on as readily after a simple meal as after an elaborate dinner. Among the intestinal symptoms are constipation, diarrhea, membranous colitis, gaseous distention, and especially certain tender areas over the colon. The diagnosis is based on the exclusion of organic disease, with variability in the test-meal washings and the absence from them of excessive mucus. A depressed nervous condition must not mislead, as this often accompanies other gastric troubles. The treatment consists of rest, seclusion, overfeeding, gentle massage of abdomen, and electricity, for from four to eight weeks; then healthy out-door exercise and diversion, with plenty of nutritive and tempting food. As a tonic sodium glycerophosphate with strychnine should be given; and if the gastric juice is deficient add hydrochloric acid and pepsin, or papain. Keep the bowels open by exercise and massage, aided, if necessary, by cascara or aloes, or, if the tendency is to hyperacidity, by calcined magnesia or sodium sulphate.

Serotherapy in Tuberculosis.—The use of serum

from an immunized animal (usually the horse) in the treatment of tuberculosis was begun with a great deal of hope and expectation a few years ago, but soon fell into disuse, owing to the unfavorable results so often reported and, especially, on account of the danger of lighting up new processes where the germ had probably become inactive. P. Paguin (*N. Y. Med. Jour.*, Feb. 10, 1900) has, however, persisted in this method of treatment and claims for it remarkable results. He gives a report of twenty-nine cases of undoubted tuberculosis of the lungs, throat, bones, joints, kidneys and testicles, many of them having been pronounced hopeless, which, after being subjected to serotherapy, entirely recovered and have remained well from three to four years. He advises, however, combining many of the usual symptomatic methods of treatment and climatic influences, where possible, with the use of the antitoxin serum.

Phototherapy.—The effects of light on the skin are twofold: It kills any bacteria present and sets up an erythema due to the ultraviolet rays of the spectrum. V. Bie (*Therap. Monatshft.*, Jan., 1900) divides phototherapy into negative and positive. In the former the ultraviolet rays are prevented from reaching a skin which is already the seat of a dermatitis, while in the latter these same rays alone are used for their parasiticidal action in the various disease of the integument. Negative phototherapy has been found to be valuable in smallpox. If only red light be allowed to fall upon the skin of patients suffering from variola, many of the pocks will not go on to suppuration and, consequently, the constitutional symptoms will be less severe, the fever of suppuration mild or absent, and the subsequent scarring not deep. In measles, also, the symptoms will be mitigated, and it is probable that in many other exanthemata the results will be no less brilliant. In applying positive phototherapy, the ultraviolet rays, which may be obtained from sunlight or an electric lamp, should reach the skin after having been concentrated by a special lens. The best results have been obtained with the skin in an ischemic condition. The indications in general are that the disease be superficial, local, and of bacteritic or fungous origin. As far as results are concerned, lupus vulgaris, no doubt heads the list. The treatment here is not painful, the recurrences rare, and the cosmetic effects excellent. Lupus erythematosus is less amenable to treatment, but alopecia areata generally yields.

Gastro-intestinal Infections in Infants.—According to I. A. Abt (*Medicine*, Feb., 1900), a simple form of indigestion in breast-fed children is caused by some alteration in the mother's milk, such alteration being due to the occurrence of menstruation during lactation, to acute illness, or to emotional excitment. If the mother's milk is rich in proteid, the child may suffer after each feeding from flatulence, colic, and diarrhea. Such simple dyspepsias are often the predisposing condition leading to gastro-intestinal infection. The undigested and fermenting food material furnishes a pabulum which favors the growth and development of the micro-organisms introduced with the food, or already present in the alimentary tract. Bacteria not pathogenic may under abnormal conditions so increase in number and activity as to cause irritation either of themselves or by their products. Thus the intestinal wall becomes injured, the micro-organisms gain access to the blood and lymph channels, and constitutional symptoms supervene. These latter may also be due to the absorption of the products of decomposition of albuminoid material. In all cases of severe intestinal disorder there is great increase in the number of intestinal bacteria, and it is possible that in most instances these are merely diplococcoid or other modified forms of the bacillus coli communis.

Infectivity of Malignant Growths.—G. B. Smith and J. W. Washbourn (*Edinburgh Med. Jour.*, Jan., 1900) consider heredity, nervous influences, trained, etc., of importance as predisposing factors in the growth of neoplasms, but unsatisfactory in explaining the phenomena of malignancy. Cohnheim's embryonal theory explains certain tumors, enchondromata of bone, dermoid cysts, etc., but again fails to explain malignancy. Chronic inflammation and irritations are important factors in the etiology of neoplasms, and the lines of distinction between inflammatory hyperplasias and neoplasms are not clearly defined. The factor of malignancy is still unexplained. Instead of non-specific irritants, may there not be some definite specific cause of the disease, which by its continued stimulus will account for the progressive growth, locally and in distant parts? There are certain positive evidences, clinical and experimental, of the infectivity of growths; many cases of inoculation have occurred in man, either from contact of a healthy with a cancerous surface, or as a result of operative interference. The possibility of reinfection during operation is so great that malignant cases must be dealt with exactly as if they were infective. Transfer from one to another part of the same individual is possible. With reference to infection from one individual to another, cases present themselves from time to time that are hard to explain by any other assumption. Guelliot collected seventy-seven cases in which there was strong reason to suppose that one person had been infected from another and in seventy-one of these the two affected were husband and wife. Still more remarkable are the localized cancerous outbreaks investigated in England and some of the continental countries, series of cases occurring in the course of a few years in a house or neighborhood. Locality is a distinct factor in the prevalence of cancer. Shallow, low-lying vales, liable to floods and composed of clays, seem to favor the development of cancer. Whether this is due to depressing of the bodily functions, or as aiding the development

of an efficient cause is not known. Experimentally, inoculations from one to another animal of the same species have been very successful. Transference between different species is difficult, yet a few authentic cases are recorded. In many cases the inoculated neoplasm developed for a time and then underwent retrograde changes and disappeared. For a certain length of time thereafter the animal was immune to further inoculation. In certain other cases the inoculated material showed all the signs of malignancy. In the cells of neoplasms, especially in carcinoma, bodies not present in other lesions are found having the characteristics of micro-organisms of the lower animal or vegetable kingdom, but evidence is still lacking to connect them definitely with the causation of these tumors.

Perforated Gastric Ulcer.—M. Richardson (*Phila. Med. Jour.,* Feb. 3, 1900) says the most constant and important symptom of perforated gastrict ulcer is agonizing epigastric pain, radiating in various directions. Without shock or other sign of peritoneal disturbance, however, this pain has little significance. Accompanied by shock and tenderness the pain strongly indicates gastric perforation, although it may be due to acute pancreatitis, acute cholecystitis, rupture of hepatic abscess, perforation of duodenum or transverse colon, etc. Without pain, acute epigastric symptoms cannot be caused by a perforated ulcer. Within a short time the symptoms of septic peritonitis present themselves. Immediately the diagnosis is reasonably certain, surgical intervention is imperative. A generous median incision gives the most satisfactory view of the abdomen.

If gas is in the peritoneal cavity, one looks for perforation, first, of the stomach, then of the tranverse colon, and, finally, of the duodenum. Having found the perforation, one must decide as to the further technic and nothing requires greater balance of surgical judgment than to select for each case of perforated ulcer the method which will give the greatest safety as to life, and at the same time the speediest recovery possible under the circumstances. Very few cases are in good enough condition to permit of excision of the ulcer and neighboring diseased tissue followed by suture. Direct closure by inverting the edges of the ulcer is simplest and safest. A series of Lembert sutures with a good bite are inserted and then tied while the stomach wall is inverted. They are less apt to tear out than if they are tied one by one, as inserted. A second reinforcing series is then used. When the wall is so infiltrated as to prevent inversion and suture, one must simply provide drainage, and wall off the general peritoneum with gauze. In one case a tight-fitting soft drainage tube was passed through the ulcer into the stomach and provided for drainage, for lavage and gavage. In other cases gauze drains may be passed down to the perforation. The infected peritoneum should be carefully cleaned, and the general cavity protected by gauze and drained when necessary. When the ulcer is inverted and sutures placed, a gauze drain should be carried to the suture line to provide for leakage or tearing out of the sutures. For forty-eight hours feeding must be by rectum, and then small quantities of liquid by mouth may be given. Gastric fistula sometimes occurs, but usually heals spontaneously.

Sexual Function; Insanity and Crime.—There is no more vexed question than this of the relationship that affections of the generative organs in women bear to insanity and to crime. H. MacNaughton-Jones (*Med. Press and Circular,* Jan. 31, 1900) concludes an extended series of observations bearing on this question, as follows: (1) The correlation of insanity and disordered sexual functions arising out of affections of the generative organs is a factor to be taken into serious consideration in the treatment of women mentally afflicted. (2) That where there is ground for the suspicion that some physical condition of the uterus or adnexa exists a careful examination should be made. (3) That in the investigation of criminal acts committed by women, either during the menopause or while the menstrual function is either active or suppressed, due weight should be given to the influence exerted by its irregularity or abeyance on the mind of the woman. (4) That the special dangers of the climacteric period and the symptoms indicative of threatening climacteric mania must be recollected. The principal of these are moroseness and depression of spirits, attacks of hysteria, occasional hallucinations of sight and hearing (especially of smell), suspicions with regard to relations, unjust dislikes, unfounded apprehensions of some great crime committed or injury inflicted on them, suicidal tendencies. (5) That in operations on the female generative organs there is a greater predisposition to mental disturbances than after other operative procedures, but the post-operative insanity is generally of a temporary nature. (6) That women who have been previously insane are predisposed to a relapse by the development of disease in their sexual organs, and especially to such temporary recurrence of insanity after operation on these organs. (7) In order to anticipate suicidal impulse and the commission of crime, the disordered mental symptoms exhibited at the menstrual epochs and at the climacteric should be carefully noted, and if the discharge or the cessation of the sexual function be attended by evidence of disease in the sexual organs, an examination of these should be made, and, if gross lesions be detected, operation should be resorted to.

For Obstinate Constipation.—

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada.

POSSIBILITIES OF CURE IN DIABETES.

THE modern treatment of diabetes mellitus is encouraging. Instead of the simple absolute withdrawal of all sugar-containing articles from the dietary, there is the rational selection of a food program to which it is possible to persuade a patient to submit without the insistence so necessary under the old régime. Careful study of the amount of glycosuria under a diet containing definite amounts of carbohydrates shows just to what degree the patient's faculty for the absorption of sugar is disturbed. Slightly less than the amount of starchy foods that can be utilized by the system is then allowed. From time to time several days to a week of absolute abstention from all substances containing sugar is insisted on. For several days twice a year a rather liberal diet of carbohydrates is allowed and the systemic metabolism, as far as it regards sugar, carefully estimated once more. Where the dietary regulations have been carefully followed it will often be found distinctly improved in the interval, the system having become able in the meantime to dispose effectively of more sugar than before the treatment was begun.

Where improvement is noted patients are very much encouraged to go on with the careful observation of the regulations. Before the possibility of the restoration of the metabolic faculty for sugar was realized, a lifetime of almost hopeless self-denial seemed the price of health. Now there is a definite term and an encouraging progress, the steps of which can be demonstrated. Any one who knows how liable diabetic patients are to be disheartened at the constant sacrifices required by their ailment, will appreciate the importance of this new aspect of the therapeutics of the disease. The mental state, as is well known, always has great influence on the course of a diabetes. To substitute, then, for the sense of hopelessness so apt to be engendered by constant denial a reasonable prospect of improvement and eventual cure is of itself a most important element in the successful therapy of the disease. The hope inspired in patients that they will ultimately regain their faculty for the metabolism of sugar is not merely illusory, nor is its justification to be found only in its suggestive influence. Such careful clinicians and thorough specialists on the subject as Von Noorden and Naunyn have reported not a few cases in which patients regained their normal metabolic relation to sugar.

The secret of many of these cures, besides the careful regulation of the amount of starches and sugars consumed, lies in the judicious use of the fats. In modern life there has been a departure from old habits in the use of fats in the diet and a substitution of the starchy carbohydrates that is the source of a good many inconveniences. A certain distaste for fats is acquired by many people and an important article of food neglected. Diabetics must be first of all taught to use fats in abundance. They are the only substances that can succeed in stilling the craving for the starches and sugars and can properly replace them. As the result of the insistence on this important principle and the thoroughly rational treatment of the question of limitation, not negation, of starchy foods, a very promising vista is opening up in a field of therapeutics that has been up to the present time a source of a good deal of dissatisfaction to patient and physician.

WAR-TAXES ON BEQUESTS.

A PETITION is about to be presented to Congress asking for an amendment to the war-tax bill of 1898, remitting the present exorbitant tax upon bequests to educational, charitable and religious institutions. According to the terms of

the law as now in force one-tenth of all such bequests go to the general government. The country is certainly not in a condition to take tithes with any propriety from moneys voluntarily donated to endow or found universities, seminaries or hospitals.

The finances of the Government for the last year, far from showing a deficit, exhibited a handsome surplus. At the present time there is talk of remitting some of the minor forms of tax, as those on express receipts and telegrams. Surely it would contribute more to the commonweal to retain these taxes for the present, if necessary, and give the bequests destined for public charities in all their entirety to the legatees. There is some danger that the much talked of wealth of many of the educational and charitable institutions that are petitioners in this matter may give color to the idea that such a remission of taxes is not demanded by the circumstances. Medical men as a body best appreciate of how much public utility these educational and charitable institutions really are. It devolves on the members of the medical profession, therefore, to bring to bear upon legislators whatever influence they may have in so good a cause. As long as the present generation is ready and willing to assume its own burdens the discounting of the heritage of posterity is absolutely unwarranted.

DIAGNOSTIC VALUE OF "KOPLIK'S SPOTS."

We presented to our readers last June the first colored reproductions that had ever been published of this important diagnostic sign. The review of the recent literature of the subject and the discussion at the last meeting of the Section on Pediatrics of the Academy of Medicine (see p. 239) show that the new symptom is attracting the attention it deserves. Although the spots were noticed many years before Koplik described them it is to his efforts that the present widespread interest in them is due and it is he who first made the claim that they are pathognomonic of measles; that they occur usually several days before any other typical symptom of the disease and are, therefore, of the greatest value in its early diagnosis. Moreover, Koplik's publications have aroused interest in the possibility, by the early recognition of these spots, of lessening the spread of measles by the immediate segregation of the children upon whom they are discovered, though they may have no other manifest symptom of the disease.

That these bluish-yellow spots with red areolæ on the mucous membrane of the cheek possess the diagnostic importance that is claimed is no longer open to question. At most of the children's clinics here in New York City, and at many throughout the country, this sign is constantly looked for and is confidently considered as pathognomonic. From many important children's clinics in Europe, notably at Berlin, Vienna, Prague and Heidelberg, confirmatory reports of the diagnostic value of the spots are published. At Prague the spots on the inside of the cheek have been seen as long as six days previous to the cutaneous eruption of the measles. They have never been seen in any other disease. Especially are they of value in making it possible to recognize measles when, owing to the circumstances of the case, scarlet fever may be suspected.

In this country the idea has been growing more and more prevalent of late years that German measles and ordinary measles are frequently confounded. We called attention not long ago to the fact that Professor Gerhardt of Berlin found among his students 15 per cent. of second attacks. Some claim that one of the two presumed attacks of measles is really an anomalous case of German measles. This is an important practical question since on it depends the freedom with which children who have presumably had one attack of measles may be exposed to the contagion again. The only feasible way to decide the question is to note carefully the occurrence of Koplik's spots. They have never been seen in German measles..

The *Baltimore Medical Journal* (February, 1900) has done some most commendable work in reproducing the colored plates originally presented in our issue of June 3, 1899, and publishing the replies of twenty prominent pediatrists of whom it had asked the personal estimate of Koplik's spots. The editor gives the following summary of these replies:

Of the 20 observers, 6 characterize the sign by the word "pathognomonic:" Hirsh, Libman, Lichtenstein, Ross, Sobel, Zahorsky.

The sign is diagnostic when present, according to 17 observers: Adriance, Blackader, Blanton, Cheney, de Saussure, Gilbert, Hirsh, Libman, Lichtenstein, Mitchell, Morse, Ross, Sobel, Taylor, West, Zabriskie, Zahorsky.

These three doubt its diagnostic value: Adams, Cameron, Cotton.

Absence of the spots excludes measles, according to 7 observers: Hirsh, Libman, Lichtenstein, Ross, Sobel, West. Zabriskie.

Absence of the sign does not exclude measles, 5 observers: Adams, Cameron, Cheney, Morse, Zahorsky.

The sign has been observed in advance of the eruption by 13: Adriance (20 cases out of 96), Blackader (in every case), Cheney ("frequently"), Gilbert, Hirsh, Libman, Lichtenstein (as early as 3 days before the eruption), Morse, Mitchell (48 hours before the eruption), Ross, Sobel (from a few hours to 5 days before the eruption), West, Zabriskie, Zahorsky.

ECHOES AND NEWS.

NEW YORK.

The State Hospitals.—A bill passed the Assembly February 9th appropriating $406,291 to reimburse the Maintenance of Salaries and Wages-Fund of the State hospitals and to purchase additional lands.

New York Hospital.—A poor woman was recently knocked down on Fifteenth street by a New York Hospital ambulance and killed. The children of the woman have begun suit against the hospital for damages.

Dr. Hammond.—The Neurological Society has passed resolutions appreciative of the estimate its members place upon the work of the late Dr. William H. Hammond and the services he rendered to neurology and psychiatry.

The Late Dr. Ketch.—At a recent stated meeting of the Medical Board of the Montefiore Home resolutions were passed expressive of the loss sustained by the Board in the death of Dr. Samuel Ketch and of the respect and esteem in which he was held.

Quarantine and Public Health.—The contest of authority between the State Quarantine and the City Board of Health, which occurred recently in reference to the coffee ships arriving from Brazil, has given rise to a bill which has been introduced into the Legislature designed to prevent such situations in the future.

Hospital for Deformed Children.—A bill was introduced in the Assembly at Albany on February 8th which provides for the establishment in or near New York City of a State hospital for the care of crippled and deformed children. Five managers, one of whom shall be a surgeon of experience in orthopedics, are to be in control.

American Red Cross Recruits.—A hospital corps composed of skilful physicians, nurses, and other attaches, has been organized in the United States for service in South Africa. The equipment, uniforms, tents, surgical instruments, and forty tons of medical supplies, have been secured. The expedition sailed from New York February 15th for the South African Republic.

Contagious Diseases.—For the week ending February 10, 1900: Measles, 859 cases and 39 deaths; diphtheria, 286 cases and 55 deaths; laryngeal diphtheria (croup), 23 cases and 12 deaths; scarlet fever, 257 cases and 23 deaths; chicken-pox, 36 cases; tuberculosis, 186 cases and 175 deaths; typhoid fever, 14 cases and 10 deaths; cerebrospinal meningitis, 5 deaths.

Animal Tuberculosis.—The Ways and Means Committee of the Assembly have reported favorably a bill providing for the inspection, by the State Commissioner of Agriculture, of stables where cattle and sheep are kept, and for the establishment of a code of sanitary rules. To him is also given the power to condemn and destroy animals afflicted with tuberculosis or other dangerous disease.

Collusion with Undertaker.—John W. Keller, Commissioner of Charities, suspended the night watchman at Bellevue Hospital and the driver of a Harlem Hospital ambulance on the specific charge that they were being paid by undertakers for tips on deaths that occurred. This information enabled undertakers to get the work of burying the body. One undertaker is reported as stating that the Bellevue trade alone was worth $50,000.

Flushing Hospital.—It may be necessary to close the doors of the Flushing Hospital. Under the present rate of payment made to the hospitals for public patients by the city the institution finds itself running heavily into debt. The city allows only 80 cents a day for surgical cases and 60 cents for medical cases. During January last the income from the city was $200, while the expense of maintaining the hospital was nearly $1000. The hospital has no fund to draw upon in case of a deficit.

Broken Neck Mended.—Some time ago we gave an account of a man, a hod-carrier, who fell from a building last October and broke his neck. He was first treated at his house by a physician, but was left with his right side paralyzed. In the early part of December he hobbled to St. Joseph's Hospital at Yonkers; a skiagraph showed that a cervical vertebra was fractured and pressure was being made upon the spinal cord. The treatment by extension was successful and the patient was discharged cured February 6th. He intends to resume his work as hod-carrier.

Obituary.—Dr. Abbie Hamlin MacIvor, wife of General James P. MacIvor, died February 8th, at her residence, 716 East 138th street. She graduated as a physician in 1886, and subsequently became an examiner in lunacy, medical examiner of teachers for the Board of Education, and a member of the County and State Medical Associations. In 1895 she was appointed a school inspector and in 1897 was elected chairman of the Board of School Trustees of the 23rd Ward. Besides her husband, she leaves a son, Dr. James Hamlin MacIvor, who practises in this city, and a daugher.

The Woman's Hospital.—The Forty-fourth annual report of the Woman's Hospital for the year ending September 30, 1899, has just been distributed. From this we learn that there were treated in the hospital during the year 865 patients. One hun-

dred and ninety-nine patients were subjected to abdominal section, of whom 189 recovered and 10 died, a mortality of 5 per cent. Among the causes of death we find 6 of them assigned to shock. It would be interesting to know if the surgeons regard shock as the result of hemorrhage. The record of abdominal work is certainly a great improvement over former years.

Medicine in New York in 1800.—Dr. Sydney H. Carney, Jr., in a paper which he read at the last meeting of the New York Historical Society, stated that in 1800 there were ninety-four physicians in New York City. They "all used that staff of medical propriety, a gold-headed cane. Small clothes were rapidly disappearing and pantaloons were covering a multitude of shins." There were in 1800 five medical schools in the United States, *viz.*, at Columbia College, at Philadelphia, Cambridge, Dartmouth and Lexington, Ky. In 1798 sixteen doctors lost their lives in trying to mitigate the sufferings caused by the plague. The pay of doctors at Bellevue was then twenty shillings a day. This hospital was three miles out of town. For a visit the fee charged was $1, for a visit and a dose, $1.25. Pills were 12 cents. Doctors got $1 a mile for going out of town. It cost $3 to get one to Brooklyn and $10 to have one visit Staten Island. For bleeding a charge of from $1 to $5 was made.

The Insane in the State Asylums.—The annual report of the New York State Commission in Lunacy shows a decrease in the per capita cost of maintaining the insane during the last year, the rate falling from $185 per annum in 1898 to $178 in 1899. The net annual increase of cases was only 529, the smallest in five years. The total number of insane in the State institutions at the close of the year was 21,374. The total amount expended for maintenance was $3,875,323, and for new buildings and equipments and for extraordinary repairs $1,127,501. The total number of patients discharged recovered during the year was 1009, and 931 additional patients were discharged sufficiently improved to enable them to return to their friends. During the year the Commission succeeded in returning to other States and countries 168 insane persons who had either been shipped to the port of New York from foreign countries or had drifted within the borders of the State from Canada or surrounding States.

PHILADELPHIA.

Health Report.—Deaths in the city for the week ending February 10th were 531, an increase of 24 over last week and a decrease of 38 from the corresponding week of last year. Contagious diseases: Diphtheria, 126 cases, 23 deaths; scarlet fever, 94 cases; 7 deaths; typhoid fever, 56 cases, 6 deaths.

Examination Frauds.—The State Medical Board has completed its investigation of the alleged fraudulent obtaining of questions by recent candidates for license and a report will soon be made. Something of a sensation is looked for, although rumors as to the extent of the affair have been greatly exaggerated. The questions for further examinations by the Board will not be printed, thus diminishing the chances for leakage.

Physicians Inspect Colleges.—A number of physicians connected with the schools of medicine in New York, Boston, Chicago, and Baltimore, visited the city last week. In the party was President William R. Harper of the University of Chicago. The various medical colleges were inspected as to their facilities, methods of instruction, etc. During their stay Dr. H. A. Hare entertained the members of the party at luncheon.

Experimental Filter Plant.—Designs are under way for the experimental filter plant which is to precede the establishment of a general filtration of the city water supply. Officials have inspected plants at Lawrence, Mass., and Albany, N. Y., prior to drawing plans. Chemical tests will be made to determine the kind of sand best fitted to meet the conditions found in the waters of the Schuylkill and Delaware Rivers.

Laloo.—This Indian freak, who has a partially developed twin attached to his chest, is now in the city and rumor has it that he will undergo a surgical operation in the near future for the removal of the appendage. The subject is causing considerable interest in medical circles, as the case would be a unique one. There is a strong suspicion, however, that the report is a perennial advertising scheme. As the freak is genuine and well worth seeing the truth of this will not be so disappointing to the public as to the surgeons, who wish to study the case.

Baggage Disinfected.—The baggage of 238 steerage passengers of the "Switzerland," which arrived from Antwerp February 10th, was seized at the Reedy Island quarantine station and will be held until it is fumigated. This action was due to the fact that the captain was unable to produce a consular certificate that fumigation of the baggage had been carried out before the ship sailed. Although all the passengers were in good health in this instance, the quarantine officials are using every precaution to prevent disease-carrying ships gaining access to this port.

Jefferson College.—The trustees of this institution are preparing plans for the erection of a new hospital on the site of the old college building. The new structure will be 107 by 276 feet in size and will correspond architecturally with the splendid college building erected last year. The feasibility of providing double facilities for the instruction of class sections by having two clinics running simultaneously in each department is being considered. The completion of the new hospital will enable Jefferson to utilize to much better advantage the vast amount of clinical material which it possesses.

Movable Kidney.—Dr. John B. Deaver believes in but one operation for anchoring the kidney,

i.e., the use of gauze without sutures. He has seen abscess of the kidney follow suturing of that organ, although clean surgery was done. Senn's method, with one or two modifications, is used. For scarifying the kidney a scalpel, instead of a needle, is used. The wound is repacked two or three times, this covering a period of about three weeks. The first packing is removed at the end of a week or ten days. The secondary packings are not inserted so deeply as the original one at the time of operation.

Pennsylvania Hospital Clinic.—Dr. J. M. Da Costa, while discussing uremia recently, called attention to the fact that urea may become locked up in the system and prevent recovery after a normal amount of urea is being excreted by the kidney. An interesting case, seen in consultation, was cited. Some time after a typical attack of uremia the amount of urea excreted by the patient went up to normal yet the patient did not get well, the stupor and curious delirium of uremia continuing. After some days the urine suddenly rose to 70 ounces per day and at the same time 1200 grains of urea were excreted. From that time the recovery of the patient was rapid.

Municipal Hospital.—Largely through the efforts of the Philadelphia County Medical Society this hospital is now accessible to the junior students of the various medical colleges of the city. Bedside demonstrations of contagious diseases, including scarlet fever, diphtheria, smallpox, leprosy, etc., are given to small sections by the chief physician, Dr. William Welch. Aseptic caps and gowns are worn by the students and every precaution taken to prevent infection and the dissemination of contagion. This new departure adds materially to the facilities of the city for medical teaching and students of medicine and the public are alike to be congratulated because of this action of the authorities.

CHICAGO.

Chicago Neurological Society.—At the annual meeting recently held, Dr. Henry M. Lyman was elected president, Dr. Hugh T. Patrick, vice-president, and Dr. Charles H. Lodor, secretary.

South Chicago Hospital.—A movement has been started to raise funds for the erection of a hospital at Calumet Heights. There is need of such an institution in that district.

Medical Societies' Joint Meeting.—At a joint meeting of the Chicago Society of Internal Medicine and the Chicago Medical Society, held January 31st, the subject of typhoid fever was discussed from various aspects.

Medical Examiners' Association.—The annual meeting was held January 30, 1900. The following officers were elected for the current year: President, Dr. Denslow Lewis; vice-president, Dr. W. K. Harrison; secretary, Dr. George F. Butler, and treasurer, Dr. J. Homer Coulter.

Ordinance for Examining Automobile Operators.—Health Commissioner Reynolds will require that operators of automobiles shall have good sight, sound hearing, and a sufficiently stable nervous system to enable them to exercise common sense under excitement, or in case of emergency.

Hospital for Consumptives.—The citizens, committee, having in charge the erection of a hospital for the treatment of consumptives, has received nearly $15,000 toward its erection. The committee is working for a fund of at least $25,000. The hospital will be constructed to care for three hundred patients.

St. Luke's Hospital.—February 16th an entertainment will be given at the Fine Arts Building for the benefit of this hospital. It is said, that, owing to its present limited income, this institution, to avoid a deficit, has been obliged for the last year or so to keep nearly sixty of its one hundred and seventy beds empty.

Passavant Memorial Hospital.—The proceeds of a recent entertainment given at the residence of Mrs. Potter Palmer were given to this hospital. This well-known charitable institution was founded prior to the great Chicago fire of 1871 through the earnest and tireless efforts of the late Rev. W. A. Passavant. At first its equipment was primitive, and its capacity limited to fifteen beds.

Relief Corps for Boer Army.—An ambulance corps under the direction of the American Red Cross Society left Chicago February 11th for South Africa to succor the wounded Boers. The expedition will be under the medical direction of Dr. John R. McNamara. The Chicago doctors who will go on this mission are Drs. T. M. Aderhold, A. F. Conroy, J. J. Slattery, Hubert H. McAuley, and Ross D. Long.

Vital Statistics.—There were 504 deaths during the week ended February 3rd, 22 less than for the corresponding week of 1899, but 18 more than for the week ended January 27th. Of the 504 deaths pneumonia was responsible for 113. For no week this winter has so great a number of deaths been reported from pneumonia, but the total is considerably below the "high week" of 1899. The medical school inspectors found it necessary to exclude from school only 291 pupils last week, as compared with 452 for the previous week. One of the inspectors sent home a marked case of chicken-pox, the patient being the son of a well-known physician.

Complications of Typhoid.—Dr. George W. Webster says that the most important complications in connection with the circulatory organs are endocarditis, pericarditis, myocarditis, arterial and venous thrombosis, embolism and hemorrhage. In the treatment of acute endocarditis, the most important factor is absolute rest, physical and mental, sufficient sleep, and reasonable freedom from pain. When the heart's action is becoming enfeebled,

there is restlessness, some breathlessness, pain and anxiety, there is often a temptation to give digitalis. This should not be done because of its uselessness and danger. The same holds true with regard to myocarditis. Opium in some form, either morphine or heroin, is the most valuable drug in the treatment of acute endocarditis. The next in order of efficiency and value are sthychnine, oxygen, ammonia, caffeine, camphor hypodermically in sterilized olive oil. Nitroglycerin is useful in cases in which the blood pressure is too high.

Treatment of Typhoid.—Dr. Frank Billings, after referring to the bacillus typhosus as the cause of the disease, says that as flies are now known to be carriers of typhoid and other contagions, all food exposed to possible infection by these pests should be thoroughly cooked. After the discharge of the patient, the mattress, the blankets, etc., should be thoroughly aired in the rays of the sun and, if soiled, should be disinfected by steam heat. The bed should be washed with hot water and soap. The production of artificial immunity against typhoid fever as a prophylactic measure by inoculation with typhoid cultures, or with typhoid serum, has been practised on man and animals with apparent success. At present the specific treatment of the disease is on trial. The success, however, thus far obtained is sufficiently good to give hope of still better results. For the present we must continue the management which modern medicine has shown to give the best results. The form of the disease today in the large cities is milder than that of the first eight decades of the century. Fewer cases now present the typhoid states and severe intestinal symptoms. The mortality-rate must vary with the degree of severity of epidemics. The lessened rate of mortality is due partly to the present milder form of the disease. Mortality statistics based upon any form of drug treatment are misleading. The specific toxemia is the cause of the clinical phenomena, notably fever and the nervous symptoms. The condition of the urine in typhoid fever is a good expression of the toxic condition of the patient's blood. Good nursing is indispensable for the comfort and safety of the patient. As regards diet, the main principle is to select simple, easily digested food which will leave but little irritating residue in the bowel. The digestive power of the individual is diminished and improper food or overfeeding may result in local disturbance of the digestive organs as well as possible autointoxication. To carry a patient through this disease not only good nursing and a proper diet are essential, but it is necessary to mitigate the toxemia and to be constantly on the alert to meet the complications and accidents which may occur even in the mildest cases. The toxemia is best combated with hydrotherapy. Skin friction is as important as the application of cold. With friction a lower degree of cold may be applied. The cold pack, the cold effusion, and the cold sponge, when combined with proper friction of the skin, will be followed by much more beneficial results than if the bath alone is given with the idea of reducing temperature. Diluent drinks and colonic flushings with normal salt solution afford a more rational treatment by improved excretion than all the antipyretics and antiseptic drugs.

Typhoid in Private Practise.—Dr. William E. Quine discusses this subject under the following heads: Prevention, general management, diet, water, medicines, alcohol, antipyretic medicines, intestinal antisepsis, hydrotherapy. Theoretically the disease is preventable, and that without reference to antitoxin inoculations, but, in private practise especially and in hospital practise to a large extent also, the measures of prevention perfunctorily employed are often a mockery of science and an insult to the conscience of the profession. As to general management, the patient is to be kept, when practicable, in a well-lighted and well-ventilated room as far from the living rooms and as near to the toilet-room as possible; and the distinction between day and night is to be maintained throughout the entire course of the disease. A good trained nurse is an invaluable coadjutor. In severe cases, when the circumstances of the patient admit of it, two nurses should be employed, one for the night and one for the day. In any case the nurse should receive a reasonable allotment of time for sleep and for outdoor exercise. Milk is to be given to the extent of three pints in twenty-four hours, when it is the main support of the patient, or even more freely than this when it is well digested. Eggs are not as generally given in typhoid fever as they ought to be. The abundant internal use of water is essential to the good management of any case of typhoid fever. It promotes elimination, quiets delirium, subsultus and jactitation, and favors sleep. No intelligent physician will maintain that in ordinary cases of the affection the internal administration of medicines is an essential feature of good management. Alcohol, in quantities, sometimes that would actually imperil the life of a well man, is as irrational, reprehensible and disastrous, as is the indiscriminate use of the coal-tar antipyretics. The free and sustained use of the coal-tar derivatives undoubtedly increases the duration of the disease, including the number of relapses; and it increases liability to intestinal hemorrhage. The idea that typhoid fever can be aborted by the administration of antiseptics and purgatives is a vain dream. But it by no means follows that intestinal disinfection and drainage are either unscientific in theory or useless in practise. Any good effects produced by medicines of this class are apparently ascribable to the inhibition of putrefactive processes in the bowel and of secondary intoxications of the blood. Patients refuse the Brand method of treatment, hydrotherapy, again and again. While there can be no question as to the practical success of the method in hospital practise, its acceptability in private practise in America is certain to be of slow

growth. Two persons are required to administer a bath to a very sick adult; and if the patients be uncommonly heavy and helpless and so sick as to require repetition of the baths every few hours, night and day for weeks, the services of four attendants will be required. The necessary service cannot be commanded in poor families. No person will be attracted to the treatment by seeing it administered. The laboriousness of it; the upheaval of the household it usually occasions; the appeals, protests, commands and pitiful attempts at resistance of the patient; the shudderings and cyanosis and pinched expression of misery while in the bath and the occasional recurrence of an involuntary discharge, together with the knowledge possessed by relative cases of typhoid fever not treated in this way which eventuated in easy recovery, oppose a formidable resistance to the general adoption of hydrotherapy in private practise which can be conquered only by the slow process of education.

GENERAL.

No Yellow Fever at Havana.—Havana, after experiencing the felicity of being absolutely free from yellow fever, is again afflicted. Eight cases were reported there February 14th.

Professor Von Bergmann Ill.—Among the numerous victims to pneumonia as a complication of influenza, which is now raging throughout Germany, is the celebrated surgeon, Professor Von Bergmann of Berlin.

Hospital Ship "Missouri."—The "Missouri" after an exceedingly rough passage from Nagasaki, has arrived at Honolulu. The "Missouri" had 277 sick and wounded soldiers on board when she started from Manila, during the trip 16 died. She is en route for San Francisco.

Famine Spreads in India.—It was reported from Bombay on February 7th that the famine has rapidly become worse. Already 4,000,000 persons are receiving relief and a steady increase in the number is to be expected. Deaths from starvation are becoming frequent.

Hospital Ship "Maine."—Lady Randolph Churchill reports that the hospital ship "Maine" has carried its first load of sick and wounded from Durban to the hospitals at Cape Town. There were 140 patients on board; among these were 69 wounded and many cases of rheumatism and fever.

Smallpox through Kissing.—Charles Frank of Carpenter, Ia., during a kissing-game at a church sociable, kissed three young women. Shortly after Frank became ill with smallpox and then the three young women became afflicted with the same disease. Eight cases have resulted in all and one death occurred.

Typhus in Mexico.—The Marine Hospital Service reports that an epidemic of typhus fever is raging in the little town of Santa Maria, Mexico. The population of the village is not over 400. Previous to January 26th there had been reported 24 cases and since then a sufficient number to make a total of 60 cases.

A Change in Date.—The meeting of the American Medico-Psychological Association in Richmond, Va., will be held May 8, 9, 10, 11, and not on May 1, 2, 3, 4, as heretofore announced. The change in date is made to enable members to attend the Congress of American Physicians and Surgeons in Washington, May 1-4.

Skin-Grafting Suit.—Injuries to Miss Susie Kelly of North Adams, Mass., necessitated a skin-grafting operation, which was done by Dr. M. M. Brown, Miss Rose Murphy permitting Dr. Brown to take from her skin the necessary grafts. After the operation Miss Murphy sued Dr. Brown for taking more skin from her body than she authorized him to take. The Court decided in Dr. Brown's favor.

Leprosy in America.—Father L. W. Mulhane, who has done much for the lepers in the United States, has been studying the leprosy problem in Cuba. Father Mulhane considers that leprosy is increasing in Cuba and in the United States, and that it is likely to become formidable in this country by introduction from our new colonial possessions unless the Government takes steps to establish a home where the lepers can be kept isolated from the rest of the community. He believes that there are now 5000 lepers in the United States.

Disease Germs in Books.—The Scranton (Penn.) Public Library was closed during the two weeks ending February 10th, by order of the Board of Health of that city. It was feared that diphtheria and scarlet fever, which are epidemic in Scranton, were being spread by the circulation of the books. The directors asked that a daily list of contagious cases be furnished them so that they could refuse books to those with sickness in their families. The Board of Health refused, saying that the negligence of physicians has left them in ignorance of most of the cases of contagious diseases.

Resignation of Dr. Wortman.—Dr. J. L. Wortman resigned the curatorship of the Department of Vertebrates at the Carnegie Museum in Pittsburg on February 6th. The cause was a disagreement with the Rev. Dr. W. J. Holland, curator of the museum. One of the gentlemen maintained that certain bones dug from the fossil beds of Wyoming were those of the Brontosaurus, while the other insisted they belonged to the Dipsodocus Magnificus. This recalls the "Row upon the Stanislaus," which Bret Harte's verses have made memorable. Dr. Wortman has returned to his old place in the laboratory at Yale.

Book and Paper Distribution.—The twenty-fifth annual report of the Hospital Book and Newspaper Society shows that during its last fiscal year there were distributed by it 5812 books, 26,777 magazines, 71,140 weekly and illustrated papers, and more than 200,000 daily newspapers. More

than a dozen women, working two or three mornings in a week, are scarcely sufficient to distribute this material weekly to the society's beneficiaries which number over two hundred, and which include city institutions under the Charities and Correction Departments, hospitals, prisons, schools, lodging-houses, light-houses, life-saving stations, libraries in mining districts, the Army and Navy, and such people as live in remote places where there are no other facilities for obtaining reading matter.

Aseptic Vaccination.—The wide-spread foci of invasion of smallpox which exist at the present time throughout a large portion of the country necessitate an unusual amount of vaccination. It is fortunate that there is at the present time the most approved form of virus that has ever been produced in the form of glycerinated vaccine. In the use of it some modification of the old method of vaccination must be adopted. There are certain steps that should be taken and certain errors that must be avoided. These perhaps are best summed up in the form of a few "dont's" for the operator, as follows: (1) Don't prepare the site by washing with antiseptic solutions, but scrub the arm thoroughly with soap, brush and hot water, and dry with a clean towel. (2) Don't draw blood if you can help it. A gentle oozing of serum gives a much better result. (3) Don't fail to rub the vaccine thoroughly and persistently into the abrasion. (4) Don't replace the clothing until the vaccine is thoroughly dry. (5) Don't apply antiseptic dressings. By following these instructions there should not be more than one or two failures in a hundred.

Pneumonia That Only Threatens.—Under this heading Dr. George Dunsmore of St. Albans, Vt., in the *Med. Times,* takes his professional brethren to task for ignoring or cultivating the impression that such a disease exists. After narrating the story of the students, who thought to trap the professor of entomology by presenting him for classification several bugs that they had previously disemboweled, disarticulated, and reconstructed from the remains, and were informed after careful scrutiny that the specimen was a *humbug,* declares that he is very much afraid that the bug of the disease above mentioned is a similar specimen. Pneumonia, like a club, can leave no mark until it strikes and cannot strike so long as it only threatens to strike. Within a year a woman said to him, "You cannot imagine what a narrow escape I had from pneumonia. The doctor said he never saw any one come so near having it and not have it." On another occasion a patient remarked, "The doctor said I was threatened with pneumonia, and made me three visits that day; but I was only threatened with it." Query—If a threat requires three visits a day, how many would the reality need?

The "Mississippi Valley" Transactions.—The Missisippi Valley Medical Association at its last meeting, the twenty-fifth annual session, decided to preserve its transactions by publishing them in book form. The first volume, which is a compilation of the proceedings of the meeting held at Chicago, October 3, 4, 5, 6, 1899, is just at hand. In this we learn from a brief historical sketch that the society was organized in 1875 under the name of the Tristate Medical Society—the members were residents of the States of Indiana, Kentuck and Illinois. In 1883 it was found that physicians from many other States had become members, and it was decided to enlarge the sphere of the society. The name was accordingly changed to the Mississippi Valley Medical Association. At the present time the membership is really national in its scope. The present volume is a large octavo, printed in clear type, and the material is well arranged. The excellence of the papers insures for the society a place among the foremost medical associations in the country. The appearance of the volume certainly does credit to its compilers, except, perhaps, the color of the binding, which is unfortunate.

Medical War News.—Almost the only subject of interest and conversation in medical circles, as in all others in London is the war. Not a week passes but from one to a dozen members of the profession are announced as going to the front in one capacity or another. Nor is it merely surgeons and general practitioners who are volunteering, the specialists have caught the infection as well. Mr. L. Vernan Caryill of Kings College Hospital, a well-known ophthalmic surgeon on the teaching-staff of the Medical Graduates' College and Polyclinic, and Mr. L. N. Pedley, lecturer upon dental and oral surgery at Guy's Hospital, are both going out in connection with the Imperial Yeomanry Hospital. So many cases of bullet-wounds of the face and jaws have already been reported that the special skill of both these gentlemen will be most welcome and find abundance of useful occupation at the Cape. No less than twenty surgeons and forty nurses are going out on the staff of this hospital. Since the distressing reverses and blunders of the past few weeks, the English press is more and more forcibly calling attention to the fact that the one department of the army in which blood and social position cut no figure, but which is open to all who can win on their merits, the Army Medical Corps, has scored the one success of this campaign. Men, who until the most recent date were hardly recognized as "gentlemen" by the haughty combatant, and are still treated with the scantest courtesy by the War Office, have carried out their war-work with brilliant success to a chorus of universal praise. While the efforts of their social "superiors" have resulted in blunder after blunder, culminating in serious disaster relieved only by the bravery and determination with which it has been faced. And the contrast is keenly appreciated by the English people. The only redeeming feature of the campaign so far have been the steady bravery of the fighting-line and the splendid manner in which relief has been afforded to the victims of the generals' blunders.

The latest instance of the gross stupidity and hereditary genius for blundering of British officialdom has just been furnished by the attitude of the War Office in respect to the accommodation of soldiers invalided home. Months ago offers began to pour in upon them of beds here, wards there, entire homes or hotels elsewhere, but it has now been discovered that to the majority of these generous offers no definite reply has yet been sent and in some cases not even a letter of thanks for the offer, the official excuse being that they are doubtful as to the possibility of maintaining due military discipline in such scattered institutions! At the same time the Government Homes and Hospitals are confessedly utterly inadequate and the War Office is muddling about attempting to secure beds in the already sadly overcrowded London hospitals. One offer to build a home capable of accommodating 150 men close to the Herbert Hospital at Woolwich was not even vouchsafed the courtesy of a reply and has naturally been withdrawn. At least two-thirds of the estimated 3500 beds required have been offered by private generosity; 2000 casualties occurred at the front last week alone, and yet the wise men of the War Board cannot overcome their scruples as to the sacred preservation of discipline and accept the noble gift before their own limited accommodations are hopelessly overcrowded.

CORRESPONDENCE.

THE TREATMENT OF ANEURISM BY GALVANISM THROUGH INTRODUCED WIRE.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—Concerning the application of the galvanic current for its electrolytic effect on the circulating blood in the treatment of aneurism, and your kind reference in a recent issue to my pioneer work with the method, I desire to ask for space to note that one of the important facts so demonstrated is that not a *mild* (as you have stated) but a *strong* current (through the anode) may be employed with absolute safety and benefit. In respect to this in my first paper on the subject (*American Journal of the Medical Sciences,* Oct., 1892), in speaking of the inutility of mere galvanopuncture in the treatment of aneurism and of the immense superiority of the method I described, I remarked that galvanopuncture practised as advocated in text-books on electricity is useless indeed—such as a current of but 20 to 30 milliamperes, and this applied for only a few minutes. I said that "the interpolar resistance is so great with one electrode externally that an electrolytic action to any purpose necessitates a current strength and the duration of its application much in excess of this." I remarked that "fifty milliamperes are none to great nor an hour's session too long, if permanent results are to be hoped for;" that "no greater risk attends the application of a strong current and a long session provided the needles are properly insulated."

The current's strength and the duration of its passage (through the introduced coiled wire) in the cases operated on by me and in those I supervised were as follows: Case I, thoracico-abdominal aortic aneurism, 70 milliamperes for 1 hour; Case II, innominate aneurism, 80 milliamperes for 1/4 hours; Case III, innominate aneurism, upward of 70 milliamperes for 65 minutes; Case IV, abdominal aortic aneurism, 50 milliamperes for 30 minutes; Case V, thoracic aortic aneurism, 80 milliamperes for 1 hour; Case VI, abdominal aortic aneurism, 65 milliamperes for 57 minutes; Case VII, thoracic aortic aneurism, upward of 70 milliamperes for 1 hour; Case VIII, thoracic aortic aneurism, operated upon on three separate occasions, (1) upward of 80 milliamperes for 1 hour; (2) 100 milliamperes for 77 minutes; (3) 100 milliamperes for 75 minutes.

In my later papers on this subject (*British Medical Journal,* Aug. 14, 1897, and *Philadelphia Medical Journal,* Nov. 12, 1898) I have especially emphasize the fact that my experience has shown that to obtain the best results the current's strength must be high and the session long, and that "by the application of a strong galvanic current through coils of wire, so disposed that all areas of the sac are reached, it follows without exception, as has been noted in all recorded cases, that consolidation by virtue of clot-formation is promptly and invariably produced. The solidification is rapid and is generally manifest before the end of the electrical session, through changes apparent to the eye and the hand, in the pulsation and in the degree of consistence of the sac-wall. These changes become more decided in the course of a few days, until, after a time, in the most favorable cases a hard nodule, with a communicated pulsation only, replaces the previous expansible tumor."

ARE ACQUIRED CHARACTERISTICS HEREDITARY?

To the Editor of the MEDICAL NEWS:

DEAR SIR:—My excuse for troubling you with this letter is that the subject of it constitutes one of the most important questions of the present day.

The *Journal of the American Medical Association* for November 18, 1899, contains an editorial entitled the "Transmission of Acquired Characters," which is, in reality, a criticism of a paper read by an English physician, Mr. Archdall Reid, at the last meeting of the British Medical Association. This gentleman said that, "though the whole plant and animal kingdoms have been ransacked, no single instance of the transmission of an acquired character has yet been proved" to which the erudite editorial writer answers by asking, "Is he (Mr. Reid), as

it seems he must be, ignorant of the testimony of Brown-Séquard, Westphal, Romanes and others when he makes this statement?" The ignorance is elsewhere; Mr. Reid, with whom I am not personally acquainted, and who is well able to take care of himself, has written a book called "The Present Evolution of Man," a perusal of which would demontsrate his familiarity with the whole of the evidence.

Nobody outside the medical profession any longer attaches any importance to Brown-Séquard's investigations, "concerning which recent experiment and inquiry have raised considerable doubt." The quotation is from a letter by Professor Ray Lankester, published in the *Lancet* of March 6, 1897, page 696. As, however, he has not the advantage of being a member of the medical profession, his opinion will, I fear, carry no weight among physicians. It is useless, therefore, for me to mention the experiments to which he refers. Westphal was one of Brown-Séquard's assistants who produced what he was pleased to call "epilepsy" in guinea-pigs without any incision, by striking the heads of the animals with a hammer. It seems somewhat remarkable that this kind of "epilepsy" is not transmitted when other persons try this experiment. As to Romanes, a reference to page 154 of Vol. II. of "Darwin and After Darwin" (published in 1897) will show that he was very far from being convinced that acquired characters are transmitted. "In the present state of our information," he writes, "this judgment" (that acquired characteristics are hereditary) "must be deemed provisional, or liable eventually to be overturned by experimental proof of the non-inheritance of acquired characters." (Mr. Romanes died in 1894, so that it is impossible to communicate with him as to any change in his opinion after the publication of his book.)

The writer of the editorial in the *Journal of the American Medical Association* attaches much importance to Talbot's cases of Jewish boys being born already circumcised, probably because the facts are supplied by a physician. But this evidence is open to two serious objections: (1) How is it that only two per cent. of the boys examined by Dr. Wolf "were born partially circumcised" and "only six per cent. were born with a short prepuce?" ("Degeneration," by Eugene S. Talbot, p. 47). Surely, if acquired modifications are *usually* transmitted, at least sixty per cent. of Jewish boys ought to come into the world without a foreskin. (2) No careful enquiry seems to have been made in order to ascertain how many non-Jewish boys are found with a congenital absence of the foreskin.

I do not hold a brief for Weismann, and in my humble opinion many of his hypotheses are untenable. Indeed, they belong to the region of metaphysics, and are altogether outside the range of science. I cannot understand, however, in what way this admission injures the neo-Darwinian contention that, *as a rule*, acquired modifications are not transmitted. Neo-Darwinians do not assert that they never are and never can be; they leave that pleasure to the Weismannians. Almost all that we know about heredity has been learned from investigators outside the medical world; pathology is not a safe guide in questions of general biology, because diatheses play so important a part in cases of disease. An example of an easily explained error may be found in the assertion of the late Sir William Roberts (Allbutt's System of Medicine, Vol. III., page 181) that "the history of gout supplies some important instances of the possibility, so much debated among biologists, of the hereditary transmission of acquired characters."

The author of the editorial in the *Journal of American Medical Association* is evidently ignorant of what, for want of a better name, I have called "pseudoheredity,"[1] and he still writes, I suppose, of "hereditary" syphilis and not of "congenital" syphilis. The latter part of the editorial leads me to think that some medical men have not the vaguest idea of what the word "heredity" means even in pathology. It is neither the transmission of identical disorders nor of symptoms, but the passing-on from one generation to another of "organic dispositions" —(Morel).

When a host, upon which a parasite in living, undergoes starvation, the parasite often suffers. Likewise, when a pregnant woman indulges in alcoholic drinks to excess, the infant at birth and afterward, may show the results of its mother's depravity; but in neither case is there anything of the nature of true heredity, as I understand the facts. Both cases are examples of pseudo-heredity. It is possible, I imagine, that the milk of an alcoholic woman may contain alcohol, and that her infant, by the consumption of it may, at an early age, acquire a taste for liquor in this way. But this hypothesis has no suggestion of heredity about it.

In recent volumes of the Proceedings of the English Royal Society may be found accounts of a number of interesting experiments made by Mr. Walter Heape. He has succeeded in transferring fertilized ova from rabbits of one breed to rabbits of another. If the foster-mother has in any way influenced the progeny, nobody has discovered it. This evidence is unfavorable to the neo-Lamarckian hypothesis that acquired characters are transmitted, but it is by no means conclusive.

I must apologize for the length of this communication, and must explain that Mr. Reid lives in England and is not likely to see the fallacious editorial in the *Journal of the American Medical Association* in time to reply. Moreover, if there is one question which demands the attention of scientific men more than any other, it is the question which I have written at the head of this letter.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, February 3, 1900.

ENLARGEMENT OF THE YEOMANRY HOSPITAL—PRAISE FOR MR. TREVES—BRAVERY OF MEDICAL OFFICERS—LARGE BEQUESTS TO LONDON HOSPITALS—A DOCTOR'S REMINISCENCES—"FERTILIZER" PURCHASED FOR HUMAN FOOD.

So generous has been the popular response to funds for this, the latest of the war-hospitals, that the Committee announces its intention of equipping a branch field-hospital as well. The original plan of a base-hospital at Wynberg with 500 beds has already received sufficient promise of support to ensure its complete and rapid realization. The Yeomanry is a specially favorite corps with the British public, as it represents almost the first active participation in the war of the great middle-classes of society. So far the rank and file of the army have been drawn almost exclusively from the "lower" or working classes and the officers from "society" and clubland, leaving the real backbone-class of the country almost unrepresented. This defect is, however, being rapidly amended as the need of the country and seriousness of the situation becomes more clearly appreciated.

Several of the war-correspondents at the front speak in their letters in terms of highest admiration of the skill and success of Mr. Treves as an operator. He is devoting himself chiefly to abdominal operations, for which his well-known brilliant research studies and exceptional surgical experience have specially qualified him, and his successes are attracting wide attention. The reports dwell specially upon the resources shown in organizing his operations and adapting himself to circumstances and the marvelous rapidity with which one difficult and delicate operation after another is carried through without a single hitch when working under the fearful pressure of the flood of wounded upon the field of battle itself.

One result of the enormous increase in the range of modern rifles has been a serious one for army surgeons. So tremendously has the width of the "zone of fire" been increased that the surgeon must practically be almost as continually under fire as the fighting-line itself and, what is worse, carry out all his first dressings and emergency operations with the knowledge that at any moment another bullet may either render his ministrations unnecessary or put an abrupt stop to them. This would hardly seem conducive to cool judgment and precise bandaging, but Sir Wm. MacCormac especially praises the skill and efficiency with which the dressings of the wounded brought into the field-hospital had been applied, for the most part under a perfect hail of bullets. The first sign of hesitation on the part of medical officers to go wherever their services are required has yet to be recorded and many of them have received special mention for conspicuous bravery in the discharge of their errand of mercy. Among these is Surgeon-Major Babtie, who, after the annihilation of Long's battery in its reckless charge to the front, rode not merely up to the firing line but far in advance of it, across a belt which had been literally swept clear of every living thing by the storm of bullets, to reach a gully into which the survivors of the battery, including poor young Lieutenant Roberts, son of the Commander-in-Chief, had dragged themselves for shelter. His horse was killed under him, but he himself escaped in some marvelous manner and for seven hours was in sole charge of a score or more of wounded men, lying under a blazing African sun and without water, save that contained in his own bottle, which he doled out in dram doses.

One of the most generous gifts ever made to English hospitals is that conveyed by the will of the late Professor Hughes, whose death occurred in London last week. This distinguished scientist, the inventor of the microphone and of the printing telegraph-machine, both of which brought him in large royalties so that his income was estimated at $200,000 a year, left the whole of his large estate, aggregating two and a half million dollars, to the charitable and educational institutions of London. Hospitals came in for the lion's share, four of these receiving no less than $400,000 each. These four are Kings College Hospital, the Middlesex Hospital, and two others whose names are withheld. The money, however, is not to be paid until twenty years after the death of Mrs. Hughes. The testator was at one time professor of music and of scientific subjects in a little denominational college at Bardstown, Kentucky, and most of his inventions were made in America, although he was born in England.

Much interest is aroused in the profession by the announcement that Sir Joseph Fayrer is preparing a volume of "Reminiscences" which Blackwoods will publish in the spring. Apart from his brilliant services to medicine and all the picturesque associations of a lifetime in India, Sir Joseph has had a most varied and even adventurous career. He began his Indian service, for instance, by being shut up in Lucknow, through the whole of the celebrated siege and shared in the transports of the "relief," which has passed into song and story, while a large part of his life has been occupied with campaigns against cholera, plague and famine. If the book is not a success it will not be for lack of abundance of stirring episode and a great personality behind it.

A most extraordinary case of attempted sale of decayed food has just been before the police-courts here. In the cellar of a provision dealer a large number of "blown," bulging and otherwise spoiled cans of preserved meat, vegetables and fruits were discovered. Their owner alleged that he was "only going to pick them over" and sell what were unspoiled. Upon inquiry, however, it was discovered that the entire lot of 650 tins had been bought of a dealer as rubbish for

fertilizing purposes! The price paid for the collection was $5, and the dealer had not the slightest suspicion that any of them were to be sold to be used for human food. The defendant was sentenced to three months imprisonment with hard labor, the magistrate remarking that the thought of such depraved greed made him shudder.

TRANSACTIONS OF FOREIGN SOCIETIES.

British.

RUPTURE OF THE UTERUS—ALBUMINURIA OF PREGNANCY—OPERATION FOR TUBERCULOSIS OF THE SEMINAL VESICLES—PAROXYSMAL HEMOGLOBINURIA IN A CHILD—RECURRENT MALIGNANT TUMOR OF THYROID GLAND—ANKYLOSIS OF JAW CURED BY RESECTION—COMPLETE MASTOID OPERATION FOR CHRONIC PURULENT OTORRHEA—ON THE TRAUMATIC PRODUCTION OF CANCER.

H. SPENCER read a paper on rupture of the uterus before the Obstetrical Society of London January 3rd. In four cases he packed the rent with iodoform gauze introduced through the vagina. All of these patients recovered. Eight others whom he had treated by other methods died, either in a few hours from shock and hemorrhage or in a few days from sepsis. He expressed his views as follows: (1) Abdominal section is rarely required, and then only in cases in which the fetus has passed wholly or in great part into the peritoneal cavity. It should be performed rapidly under local infiltration anesthesia, and should be followed by flushing of the peritoneal cavity with normal salt solution and by suture of the tear, if possible; or, if this be not possible, by packing the tear with iodoform gauze and draining by the vagina or abdomen. (2) Abdominal hysterectomy is hardly ever necessary. When the broad ligaments are so much damaged as to endanger the vitality of the uterus, vaginal hysterectomy should be performed. (3) All incomplete tears implicating the broad ligament and almost all complete tears should be treated by packing the rupture per vagina after removing clots and fluid blood.

P. HORROCKS also reported cases in his own practise in which this method of treatment had been successful, but the success was to be attributed to the aseptic conditions under which labor had been carried out, no less than to the gauze packing. If a patient cannot be treated in this manner, the abdomen should be opened and the tear in the uterus sewed up with silk.

HERMAN advocated vaginal hysterectomy if the rupture cannot be satisfactorily treated by gauze packing. Partial suture of a uterine tear is worse than useless. The suture should be perfect or not attempted at all.

At the Edinburgh Obstetrical Society, January 10th, J. RITCHIE read a paper on albuminuria of pregnancy. Even if the amount of urine be small and not accompanied by any signs of organic renal disease, the nutrition of the child is often gravely affected. In such conditions two dangers exist, *viz.*, danger to the mother from eclampsia and danger to the child from malnutrition. For eclampsia three conditions are requisite: (1) A certain quality of the nervous system; (2) a toxemia, and (3) some peripheral irritation. Treatment, therefore, should reduce the amount of nitrogenous food, limit the production of toxic matter, and favor elimination. Rest in bed, moderate purgation, diuresis by means that do not increase arterial tension, and limited feeding seem to be the main points to be observed.

At the Medical Society, January 8th, M. MOULLIN reported two cases in which he had removed tubercular seminal vesicles through a transverse perineal incision. The disease had extended upward from the epididymis, so that the testis and cord were first removed by a scroto-inguinal incision, the cord being divided as high up as possible. The patient was then placed in the lithotomy position and the seminal vesicles and ejaculatory ducts were dissected out. There was very little bleeding. The sphincter was stitched to the centrum tendineum and the wound stuffed with iodoform gauze. Both patients recovered promptly, although one was troubled for some months by a small urinary fistula, due to the fact that the ejaculatory duct was torn out of the urethra. Moullin strongly advocated this complete operation in every case of tuberculous epididymitis in which the seminal vesicles can be distinctly felt through the rectum.

At the Clinical Society of London, January 12th, LUNN spoke of paroxysmal hemoglobinuria in children and presented a patient, aged six, the tenth of twenty-four children in whom the peculiarity was noticed when one year of age. From time to time she passed port-wine urine containing red blood-cells. She usually had a chill and collapse when an attack was imminent, but in the intervals her health wos good.

VOELKER commented on the fact that in a large proportion of these cases there is a definite history of syphilis. On examining the blood he had noticed an unusual tendency of the corpuscles to cohere, so that they formed snake-like coils, and the corpuscles themselves were elongated.

C. SYMONDS showed a patient who had had malignant disease of the thyroid and on whom he had twice operated. The interesting points were that the disease remained localized in the left lobe, and the long duration of the tumor—eleven years.

A. BARKER said that malignant tumors of the thyroid often run a chronic course, one in his own practise lasting eighteen years.

J. CLARKE showed a girl eighteen years of age, whose jaw he freed by removal of the neck of the bone on the right side. Ankylosis had been complete for three years. The patient rapidly gained flesh and was able to open the paw for an inch and to close it perfectly.

At the Royal Medical and Chirurgical Society, January 23rd, C. A. BALDWIN spoke of the mas-

toid operation for the cure of chronic purulent otorrhea. He pointed out that the selection of cases for the complete mastoid operation is surrounded with difficulty, and that large experience rather than rigid observance of any rule is the best safeguard against the risk of delay, on the one hand, and the performance of an unnecessary operation on the other. The cure of chronic otorrhea cannot be effected by simply opening the antrum. The complete mastoid operation which involves damage to the tympanic structures is inapplicable to acute cases. Intractable chronic otorrhea should be treated by two operations: (1) The operation for the removal of the disease, *i.e.,* the complete mastoid operation, and (2) the operation for the healing of the wound, *i.e.,* by the epithelial grafting of the raw bone cavity.

At the Pathological Society of London, January 16th, T. G. Stevens gave an account of the bacterial examination of a thrombosed ovarian vein following hysterectomy, the patient having died from subacute septicemia. The right ovarian vein was found to be thrombosed from the ligature to the vena cava. Cultures made from it showed colonies of the bacillus coli communis and the bacillus pyocyaneus.

W. Pakes found the bacillus proteus vulgaris in a clot in the left iliac vein of a patient dying from phthisis and tuberculous enteritis.

S. G. Shattock exhibited a specimen of "spontaneous" carcinoma of the uterus of a rabbit. The growth was of a papillomatous type and, besides many uterine foci, there were peritoneal nodules. Histologically it was columnar-celled carcinoma. The interest in the specimen was due to its bearing on the conclusions stated in a paper by L. Lack, who exposed and scraped the ovaries of a rabbit and then closed the abdominal wound. Twelve months later the animal showed signs of abdominal carcinoma and was killed. Carcinomatous nodules were found throughout the peritoneal cavity and in the lungs. The conclusion drawn at that time was that the carcinoma was due to scraping the ovaries, but Shattock's case showed that similar carcinomatous nodules may arise spontaneously and that, unless Lack's result can again be obtained, it must be looked upon as a coincidence. The dissemination of peritoneal papillomata after rupture of a papillomatous ovarian cyst is not a safe comparison, since normal characters cannot safely be ascribed to such epithelium. When the case of normal epithelium is considered, such experiments as have been made seem to oppose the hypothesis that carcinoma can be caused by the mechanical introduction of normal epithelium into the lymph spaces. The intravascular injection of gland emulsions by Lubarsch and his pupils was in no case followed by the growth of tumors. Neither did tumor formation follow the traumatic detachment of tissue whether the fragments remained *in situ* or were transplanted to another animal of the same species.

C. A. Ballance said that it is now generally recognized that the action of normal epithelial cells when transplanted into other tissues or lymph-spaces is limited. Normal cells when so transplanted have only a certain power of development, but when malignant their power is unlimited. What is this power of malignancy? Lack's experiment does not settle the question, but in the Graafian follicle there is something quite special, for if these epithelial cells come into contact with (become infected by) certain other cells, the spermatozoa, they at once take on that most remarkable power of growth which results in the development of the fetus. Lack's experiment to be of value must be repeated many times. He himself had many times thought that he had discovered a law, when further experimentation showed him that it was only a coincidence which he had hastily assumed to be a law.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON MEDICINE.

Stated Meeting, Held January 16, 1900.

John H. Huddleston, M.D., Chairman.

Plague Bacillus.—Dr. W. H. Parks demonstrated, as noted in a previous number of the Medical News (page 104) the bacillus of the plague. His specimens had been isolated from the cases recently brought to New York from Santos, in Brazil.

Dr. F. S. Fielder read a paper entitled "A Criticism of a New Method of Preparing the Skin for Vaccination by Denudation with Caustic Potash Solution."

Technic of Vaccination.—In discussing Dr. Fielder's paper Dr. Morris said that the sentimental objections of the pain and flow of blood caused by the old method of inoculating vaccine were really not deserving of the consideration which seem to have been given them in the effort to invent a new method by the use of caustic potish. The pain is really very insignificant. It is possible to vaccinate a sleeping babe without waking it. Even highly neurotic children when a little care is exercised give very few signs of pain. It is scarcely necessary to have more than a show of blood and the vaccination will take very well. The use of caustic potash will almost surely leave a scar whether the vaccination takes or not. In the case of unsuccessful inoculation this may easily prove a source of error later on and the patient thus be subjected to the danger of taking smallpox at a time when he is thought to be protected. There is no such thing as a characteristic scar of vaccination. Any physician who has had to examine many arms knows this very well. The bite of a dog, or a knife in the hands of a careless boy, may easily produce a scar that will be taken even by an expert for a vaccination-mark unless he knows the history. It is very dif-

ferent now to the state of affairs that existed when human virus was used. Then the portion of scab was inserted beneath the skin with a lancet and a rather deep scar was the result. Any one who as a boy has with a little sand produced "fox bites" on himself or others must know how easy it is to produce a scar that will resemble very much the vaccine mark left after the modern method of vaccinating.

Success of the Present Method.—The number of failures by the newly suggested method of vaccination is entirely too high. Good virus under the old method will give nearly one hundred per cent. of successful vaccinations. In about 1500 vaccinations during this last year the percentage of successful cases has been more than 95. Nearly all of the failures occurred in obstinate colored children who refused to be vaccinated and who by means of spittle and rubbing with their clothing endeavored to remove the vaccine virus as soon as the doctor's eye was turned away. Without these cases the percentage of successes would be nearly 100. By present methods there is very little danger of secondary infection. In the old days erysipelas sometimes occurred during the summer time so that it was the custom to advise vaccination during the colder months unless there was an epidemic. This rule would seem to be a good one still, although now, taking arms just as they come and without any preliminary cleansing, it is extremely rare to have any complications. In one case in which every precaution of the most extreme surgical cleanliness was taken, because the parents were very much opposed to vaccination, the child nevertheless developed a rather serious "bad arm," with swelling to the wrist and a condition that reminded one of cellulitis. Despite threatening and disquieting symptoms it recovered completely without surgical interference.

Practical Point in Vaccination.—Dr. William H. Park said that with the virus issued by the Board of Health at present it is very advisable to make only a small denudation. Over and over again where complaints have been made of the severity of the sore caused by the Board of Health's virus it has been found that the doctor neglected to read the directions issued by the Board of Health and denuded a large space, the size of a penny or more, as it was the custom to do before the present concentrated virus was used. The result in such cases was, of course, a large ugly sore that takes a long time to heal. As to the swelling which takes place after vaccination in certain cases an idiosyncrasy of the individual seems to have a good deal to do with it. Dr. Park himself was vaccinated while an intern at the Roosevelt Hospital. The arm swelled up from the region of the clavicle and scapula all the way down to the ends of the fingers. One of the surgeons pronounced it cellulitis and wished to incise it. This was not permitted, however, and the arm became entirely well without any other treatment than evaporating lotions.

Justus Blood Test for Syphilis.—Dr. D. H. Jones read a paper on the test for syphilis introduced by Justus in an article in *Virchow's Archives* in 1895. The test consists in noting the susceptibility of the red blood-cells to the action of mercury. If the patient is suffering from active syphilis a mercurial inunction or a subcutaneous injection of mercury is followed by a distinct diminution in the hemoglobin value of the blood. This diminution of hemoglobin seems to be due to the fact that a number of red blood-cells are destroyed by the mercury. Justus has tried it now in some 300 cases and it has been positive in every case of active syphilis while it has been absent in a large number of controlled cases. Dr. Cabot of Boston tried the test in some twenty cases and made a confirmatory report as to its value. The hemoglobin was found to be reduced by a single inunction from 10 to 20 per cent. Dr. Jones tried the test in 53 cases; 35 of them had a history of syphilis and 18 were used for purposes of control. Of the 35 syphilitic cases 17 were in the active stage, and of these 13 gave a positive reaction to the test and 4 did not react. In 6 cases where chancres existed without secondary symptoms the test was positive in only 1 case. In 2 cases of latent syphilis the test was negative. Of 7 cases of adenitis after chancre 5 gave positive reaction and 2 negative; in some of these cases secondary symptoms were just beginning. In one case of mucous patches, but without any history of syphilis, the test was negative. Justus claimed that his test was positive only for syphilis in the active secondary stage, so that Dr. Jones' work is confirmatory of the original report, although the test does not prove as unfailing as Dr. Justus originally announced. The test will undoubtedly be of service for diagnostic purposes but it has not the value that was claimed for it. Like the diazo reaction the test is of significance when positive but not when negative.

Hemoglobin in Other Infections.—Dr. Ewing in discussion said that active syphilis undoubtedly causes the presence in the circulation of certain toxic substances which make the red blood-cells more delicate. The absorption of mercury into the system under these circumstances acts as a globulicide and the test might very well prove of value. It is probable, however, that the action of syphilis on the red blood-cells is not specific and that other acute infections, as for instance malaria and septicemia, would produce a similar effect upon the red blood-corpuscles Before the test could assuredly have any practical value it should be tried extensively on such cases.

Dr. Lapowski said that for the success of the Justus test all that is necessary is the absorption of mercury. A single inunction of mercury or a single dose of it by any other means is sufficient for the test. Later on under the influence of mercury the red blood-corpuscles increase in number and the hemoglobin value returns to the normal.

Treatment of Vertebral Rheumatism.—Dr. H. Forrestier of Aix-les-Bains read a paper in which he described five cases of the pseudoneuralgic form of chronic vertebral rheumatism. While the text-

books mention torticollis and lumbago, very little is said of the spastic conditions induced by rheumatism in other portions of the spine. In five cases which Dr. Forrestier has had under treatment the stiffness occurred mainly in the dorsal region and the patients, as a rule, were more comfortable sitting than lying down. In some of the cases other joints were swollen because of the rheumatism and sometimes the knee-jerks were exaggerated and other nervous symptoms were present. All of the cases were benefited by douche massage, that is, by massage given while a strong douche of water, at a temperature of from 85° to 95° F., is played over the part which is being kneaded. The massage is given not gently, but with a good deal of force. The results of the treatment are encourageing from the beginning and the relief obtained seems to be lasting.

In discussion Dr. Virgil P. Gibney said that in young people, where the rigid condition of the spine develops which is so characteristic of chronic vertebral rheumatism, it is well to be sure that there is no latent Pott's disease. Such cases of tuberculous degeneration of the vertebra often run an extremely slow, insidious course without any localizing symptoms and massage would be the very worst thing for them.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held January 15, 1900.

The President, Frederick Holme Wiggin, M.D., in the Chair.

Drainage of Pyosalpinx.—A paper describing a new method of retroperineal drainage for this disease, with a report of five cases, was read by Dr. Leon F. Garrigues. The paper, with the discussion which followed it, will appear in a subsequent issue of the Medical News.

Strangulated Hernia.—Dr Parker Syms said that the prominent feature of a strangulated hernia is the constriction of blood-vessels which occurs at the point of strangulation and which will inevitably lead, unless relieved, to gangrene. This practically always fatal termination must be guarded against. The sooner measures are taken for the relief of the constriction the better. Active interference alone, and not expectant treatment, can be relied on with any assurance to save patients. In these days of aseptic surgery, when hundred of operations for the radical cure of hernia are reported without a single death and when the death-rate from abdominal operations is extremely low, there is no reason for the delay that used to be advised in these cases. As soon as the diagnosis of strangulated hernia can be made, operation should be performed. It is the progress of the disease, not operative interference, that is to be feared. The symptoms of this condition are those of acute intestinal obstruction with certain additional local symptoms. There is abdominal shock, and localized pain and tenderness over the hernial sac. Shortly after the development of these symptoms typanites manifests itself and absolute constipation sets in, except for such fecal matter as may have been contained in the large intestine below the constriction. The pulse becomes weak and rapid, with the wiriness characteristic of serious abdominal conditions. Vomiting manifests itself after some hours and consists, at first, of the contents of the stomach, then of the partially digested contents of the upper small intestine and finally of a more or less gruelly fecal matter. The Hippocratic face with pinched, drawn, anxious expression, is usually present. There is in addition a characteristic combination of fear and braggadocio in the patient's manner. That he is anxious and worried is clear, and yet he is apt to keep assuring himself and others that he is all right. This may become almost a form of delirium or hallucination. The general circulation becomes sluggish and the extremities especially give evidence of this fact. Although practically all the text-books advise it, taxis should not be employed. It always does more harm than good, and many a fatal termination or serious complication to operative interference is really due to the ill-advised continuance of more or less forcible efforts at reduction. All that should be done in this way is to put an ice-bag over the hernia and place the patient in a favorable position for the return of the hernia within the abdomen. No food should be given as long as the symptoms continue. Operation should be done before any severe symptoms set in. Confirmation of the diagnosis by fecal vomiting or collapse should not be waited for. It must be borne in mind that even gentle manipulation of a hernial sac in which gangrene is threatening may not be free from danger.

Technic of the Operation.—Usually the patients are not able to stand general anesthesia. At least, the risk of operation seems to be considerably increased thereby. Morphine and whiskey, about a half-a-grain and an ounce respectively should be administered some twenty minutes before the operation, and then local anesthesia should be employed to prevent severe pain. The incision should be free in order that the site of constriction can be seen. Even if the intestine looks gangrenous it may recover. It is not sufficient merely to place hot towels around it and wait for half an hour to see if the circulation may be restored, but the wound should be left open for a day or more and every opportunity given for the intestine to recover its impaired vitality. If the intestine looks reasonably healthy and the patient's condition warrants it, radical operation for the hernia should be done at once, following one of the many modifications of Bassini's method. If, owing to delay, the patient is greatly prostrated, simple suture may be done, or the wound gently packed. If the intestine is frankly gangrenous extirpation of the dead portion and an end-to-end anastomosis should be done at once, if the patient's condition will allow it. Should the patient be very weak, an artificial anus may be made and

the intestinal anastomosis deferred until he has regained his strength.

Diagnosis.—In the discussion Dr. Henry Roth said that the most important practical feature of this affection is its early diagnosis. On early diagnosis depended early operative interference and that would serve to reduce the mortality more than anything else. The most prominent symptoms are always the reflex changes produced by the irritation of the abdominal nerve. There is shock, pallor, cold extremities, weak heart-impulse, thin, thready pulse, more rapid than normal, and lowered temperature. The cardinal symptoms are those of shock and collapse. The pain is first around the umbilicus, as in colic, and then is localized at the seat of constriction. The tenderness is always local. The pathognomonic sign is the complete constipation. This is due not so much to actual stoppage of the flow of fecal matter by occlusion of the intestine as to a reflex paralysis that prevents peristalsis. As the indol in the feces is delayed in its passage through the intestine, it undergoes further change and is absorbed, appearing as indican in the urine. The urine becomes diminished in amount, partly because there is no absorption from the intestine, partly because there is a reflex diminution of excretion of urine, and partly because the lowered blood pressure due to shock prevents kidney function. In incarceration of the intestine the symptoms are not so severe and are more strictly localized. It must be remembered that where symptoms of intestinal obstruction or strangulated hernia occur and no tumor can be found at any of the ordinary locations where hernias occur, the sciatic and obturator regions should be carefully examined for the unusual forms of hernia. If but very few signs of a hernial tumor exist and the symptoms of strangulation are evident the patient should be given the benefit of the doubt and should be treated for strangulated hernia.

Dr. John F. Erdmann said that in these days of aseptic surgery, as soon as the diagnosis is made with assurance, the operation should be done and should be followed by the steps necessary for a radical cure. Taxis should be made only for a few minutes at most and not at all if it has been already practised by others, or, if the constriction proves on close examination to be small and hard. Morphine should be given about half an hour before taxis is attempted in order to relax the tissues. Hot applications are better than cold ones. If the taxis is unsuccessful the morphine will then serve the purpose of preparing the patient for local anesthesia. For this purpose eucaine B. is the best and most free from danger. Pain is not complained of under this agent even when the manipulations are extensive and somewhat prolonged. Sad results so often follow the use of general anesthesia that it is better as a rule not to employ it. If, after incision, the intestines seem to be very low in vitality and gangrene seems to be threatening, hot towels should be employed in order to decide whether vitality will return or not. Gangrenous intestines, when patients are very weak, may be left on the abdominal wall with gauze packed about them. The delay should not, however, be too long as the patient grows constantly weaker and as soon as reasonable reaction has set in an intestinal anastomosis should be done.

Radical Cure After Operation.—Dr. Irving S. Haynes said that if during the manipulations a tear should occur in the hernial sac, even up into the abdomen, this need not cause much anxiety. It can be sewed up or tied off. The sac should be obliterated as high up as possible after exerting traction upon it, so as to prevent the puckering and depression in the peritoneum which would predispose to the recurrence of the hernia. A portion of the sac should not be left with the idea of making a cushion of it in order to prevent the extrusion of intestine later on. It will never serve this purpose. It gradually becomes absorbed under pressure and a dimple in the peritoneum takes the place of the supposed cushion and gives occasion for another hernia. The peritoneum itself cannot be strengthened. The recurrence of the hernia must be prevented by making the abdominal wall stronger than it was before. In children the internal ring in inguinal hernia is almost directly behind the external ring. This is also the case in adults where the hernia has been large or has existed for a long time. Under these circumstances a new canal should be made, so as to restore the previous condition as far as possible and leave no opening directly from the peritoneal cavity to the abdominal wall. Where there are distinct varicosities in the cord these should be reduced in size by excision and ligature. The Bassini method seems to be the best and an absorbable suture should always be used. Silkworm-gut and wire simply act as foreign bodies and do not strengthen the tissues. In order to secure primary union there should be little handling of the tissues and where there is a good deal of fat some of it should be removed to relieve tension on the sutures. Tension nearly always gives rise, in fatty subjects particularly, to delayed union.

Prophylactic and Postoperative Treatment.—Dr. DeGarmo said that the best prophylactic treatment for strangulated hernia is the performance of a radical cure. Where the rupture is small, however, and does not come down when a light truss is employed, it may be proper to prescribe a well-fitting truss. Too much in the fitting of trusses is left to the instrument maker. It is not a shoemaker or a blacksmith who knows best how to fit a truss, although he may understand the mechanical principles on which they are made. The profession has neglected this subject entirely too much. As to the immediate prophylactic treatment of the serious consequences of a strangulation, very little can be said. Taxis has been considered of value for a long time, but patients seem to do better without it and it very seldom does any good in cases of real strangulation. Where taxis is attempted the gut should not be pushed back but should be pulled down. If the manipu-

lator can succeed in pulling out a little more intestine from the abdomen he will usually succeed and with comparative ease in reducing the hernia. After a successful operation for radical cure patients may be allowed to get up after about three weeks, wearing a bandage for a month or so, and then may be allowed to go absolutely untrammeled.

Dr. Charles N. Dowd said that it is delay and not the operation itself which causes the high mortality in cases of strangulated hernia. There art no contraindications to operation. Age need not delay the surgeon. He recently operated on a man aged seventy-five who had an enlarged prostate. The patient had been himself passing a catheter for a long time, had infected himself and had a severe cystitis, and was very debilitated. The symptoms were rather mild at first but pointed to some intestinal obstruction. There was a painful and tender lump about the middle of Poupart's ligament. It looked like an inflamed lymph node. At first the patient refused operation, but twelve hours later an incision was made and a small strangulated femoral hernia was found and promptly relieved. Two children of respectively four and six months of age, operated on for strangulated hernia, promptly recovered. They bore the operation very well and there was no necessity for hurry or for the omission of any of the usual steps of the operation. Babies stand such operations muct better than has been thought. The general practitioner is sometimes deterred from operating in cases of strangulated hernia by the memory of the long list of the coverings of hernia which he learned during his course in anatomy. In order to operate successfully there is no need to remember these, but simply to make an incision down to the point of constriction, which is usually in the external ring, in the aponeurosis of the external oblique muscle.

Dr. Hotchkiss said there is small danger if the operation is performed early. Recently on an old woman, eighty-one years of age, he operated with good result. The diagnosis is sometimes not so clear as could be wished. This is often the case in the form known as Littré's hernia, in which only a portion of the circumference of the intestine is contained in the hernial sac. The tumor is very small, almost unnoticeable. Even under these circumstances, however, gangrene with perforation and peritonitis may result. Where the symptoms are very suspicious it is safer to explore than to wait long in the hope that they may disappear.

REVIEWS.

Kirke's Handbook of Physiology. Fifteenth American edition; revised by Warren Coleman, M.D., Professor of Physiology in the Woman's Medical College, New York, etc., and Charles L. Dana, A.M., M.D., Professor of Nervous Diseases, Medical Department, Cornell University. New York: William Wood & Co., 1899.

This edition of Kirk's famous work contains but few changes. These which find a place are on the cell and in the consideration of the coagulation of the blood, in which the rôle of the nucleoalbumin, combining with the calcium salts according to Hammarsten and Lilienfeld, is thoroughly gone into. This combination, thrombin, splits the fibrogen into fibrin and fibrin-globulin, as is now believed but not entirely proven. The ductless glands are given more space than they have hitherto occupied, in accordance with the many clinical and experimental efforts of recent years. Much of the chapter on muscle nerve physiology is also new. Although this edition does not represent the English revision, it will no doubt be satisfactory to many American teachers.

A Pocket Text-Book of Physiology. By H. D. Collins, M.D., Assistant Demonstrator of Anatomy, and W. H. Rockwell, Jr., A.B., M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, New York. Illustrated. Philadelphia and New York: Lea Bros. & Co., 1899.

This little volume, although designated as a pocket edition of physiology, fulfils the purpose of a complete work on the subject after eliminating unnecessary information for the medical student or the general practitioner. The larger textbooks deal with experimental physiology which certainly cannot be included in a work of this kind. Its chapters on circulation, digestion, and particularly on the nervous system are as complete as is possible in such an edition. It is a valuable addition to the series and is up-to-date in every particular. Embryology is included in an interesting chapter. The typography is excellent.

A Blank Book for Autopsy Protocols. By Alfred Scott Warthin, M.D., Ph.D., Assistant Professor of Pathology in the University of Michigan. Ann Arbor: George Wahr, 1899.

The medical student at the University of Michigan is expected to attend twenty autopsies during the last two years of his studies, and this book is designed to facilitate the keeping of a careful protocol, which he is required to make in every case. The book is of a convenient size and can accommodate the autopsy protocols of ten cases. Each autopsy is allowed ten pages, carefully ruled for the various organs. The difficulty in employing such a book for general postmortem examinations is that it may often happen that the space given to a certain organ will be inadequate in many instances to contain the necessary description of the pathologic condition. However, for the purpose designed the book will be found very satisfactory.

A Text-book of Physiology. For Students and Practitioners. By Winfield S. Hall, A.M., M.D., Ph.D., Professor of Physiology in the Northwestern Medical School, Chicago. Il-

lustrated. Philadelphia and New York: Lea Brothers & Co., 1899.

Physiology has sounded a new note in recent years. It no longer deals simply with organ and function, but seizes for its explanation of life processes upon comparative morphology and embryology, upon the refinements of chemistry and physics, upon comparative anatomy and histology. The work under review is a fine example of this newer physiology. In style and manner perfect, it teaches its lessons from the broad standpoint of comparative physiology, it draws its deductions from experimental evidence not only, but from the cognate sciences as well. At important points historical data are added, which throw light to the reader as to the identity of familiar names and trace for him the methods and means of discovery of vital physiologic facts. If the work is a literary success, it is certainly also a scientific success in the broadest conception of the term.

There is scarcely the space at the reviewer's command which so important an issue demands. Some important elements will therefore be pointed out which will illustrate the general high trend of Dr. Hall's book. In the first place, the broad conception of physiology, which the author has, is evident in every page. One needs to read but little of the book to be convinced of this. His chapter on the cell alone is worth the price of the work, not because it is not altogether new, but because it presents the knowledge of cell structure as it is held to-day in a most perfect form. His very condemnation is admirable. Again, in the physiology of the nervous system the neuron theory is elaborately, yet briefly given; but so clearly that it must be very easily comprehensible even to the novice.

The author inclines to Schmidt's and Hammarsten's theory as to the coagulation of the blood, the ultimate sources of thrombin, on the one hand, and fibronogen on the other, being the nucleoplasm and the cytoplasm, respectively, derived from the cell protoplasm. He believes the theory of these investigators "as satisfactory as any." In the treatment of the circulation, the physics of the function is clearly depicted, as, indeed, it is of all the various functions. The chemistry of physiologic processes is emphasized in such a way that while the students will not be puzzled, more advanced investigators will find abundant material. This is well seen, for example, in the discussion of the digestive functions.

The author has seen fit not to consider the physiology of the so-called ductless glands. We think this an omission of importance in view of the great clinical interest attaching to these organs at the present time. The book-making is especially to be commended.

Taken as a whole, it has been a most satisfactory pleasure to read Dr. Hall's book. It is essentially modern, wholly scientific, and is indeed one of the few books of which one can say that every student of medicine and biology will be a gainer for having read it.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Lectures on the Principles of Surgery. Delivered at the University of Michigan. By Dr. Chas. B. Nancrede. 8vo., 398 pages. Illustrated. W. B. Saunders, Philadelphia.

Treatise on Orthopedic Surgery. By Dr. E. H. Bradford and Dr. R. W. Lovett. Second Revised Edition. 8vo., 655 pages. Illustrated. Wm. Wood & Co., New York.

A Practical Treatise on Materia Medica and Therapeutics. By Dr. Roberts Bartholow. Tenth Edition, Revised and Enlarged. 8vo., 866 pages. D. Appleton and Company, New York.

Hermann Ludwig Ferdinand von Helmholtz. By Dr. John G. McKendrick, 8vo., 300 pages. Masters of Medicine Series. Longmans, Green & Co., New York.

A Manual of the Diagnosis and Treatment of the Diseases of the Eye. 8vo., 604 pages. Illustrated. By Dr. E. Jackson. W. B. Saunders, Philadelphia.

A Text-Book of Diseases of Women. By Dr. Charles B. Penrose. 8vo., 851 pages. Illustrated. W. B. Saunders, Philadelphia.

Histology and Pathology. A Manual for Students and Practitioners. By Dr. J. J. Nichols and Dr. F. P. Vale. 8vo., 458 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York.

Christian Science. An Exposition of Mrs. Eddy's Wonderful Discovery, Including Its Legal Aspects. By W. A. Purrington. Cap. 8vo., 194 pages. Illustrated. E. B. Treat, New York.

A Manual of Surgical Treatment. By Dr. W. Watson Cheyne and Dr. F. F. Burghard. In Six Volumes. Volume II. Royal, 8vo., 382 pages. Lea Brothers & Co., Philadelphia and New York.

The Care and Treatment of Epileptics. By William Pryor Letchworth, LL.D. Royal, 8vo., 246 pages. Illustrated. G. P. Putnam's Sons, New York and London.

Mental Affections, an Introduction to the Study of Insanity. By Dr. John MacPherson. 8vo., 380 pages. Macmillan & Co., London and New York.

Practical Text-Book of Midwifery for Nurses and Students. By Dr. Robert Jardine. Cap. 8vo., 245 pages. Illustrated. Macmillan & Co., New York and London.

The Refraction of the Eye, Including a Complete Treatise on Ophthalmometry. A Clinical Text-Book for Students and Practitioners. By Dr. A. Edward Davis. Demy. 8vo., 431 pages. Illustrated. Macmillan & Co., London and New York.

The Treatment of Diseases of the Nervous System. A Manual for Practitioners. By Dr. Joseph Collins. 8vo., 602 pages. Wm. Wood & Co., New York. York.

Diseases of Women. A Treatise on the Principles and Practice of Gynecology. By Dr. E. C. Dudley. Second Edition. Revised and Enlarged. 8vo., 717 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York.

A Manual of Modern Surgery. An Exposition of the Accepted Doctrines and Approved Operative Procedures of the Present Time. For the use of Students and Practitioners. By Dr. John B. Roberts. Second Edition. Revised and Enlarged. 8vo., 842 pages. Illustrated. Lea Brothers & Co., Philadelphia. and New York.

NOTES ON PLAGUE.

BY MAJOR H. E. DEANE,
OF CALCUTTA, INDIA;
ROYAL ARMY MEDICAL CORPS.

BEFORE dealing with plague specifically in Calcutta it will be advantageous to consider epidemics of plague in other places, and what lessons can be learned from previous experience of this disase. We have to deal with a specific, febrile, infectious disorder, and plague presents the difficulties common to the other infectious diseases, with difficulties peculiar to itself, such as the length of time during which it will persist and recur in a place and its disregard of any measures adopted for its abolition or cure. There have been more epidemics of plague in the world than of any other disease; and it has been widely spread, devastating whole populations.

General View.—It is believed to have first appeared in the Delta of the Nile, in A. D. 542, and spread over Egypt to Constantinople, where it is said 10,000 people died in one day. It spread over the whole Roman Empire and north of Africa in the succeeding century. In the fourteenth century nearly the whole of Europe and England were over-run by the plague, one-fourth of the population of Europe, 25,000,000, being estimated to have died. It recurred in the fifteenth century in Europe and England, and Henry VII. left London for France, on account of a bad epidemic there. The same story is told of the sixteenth century, in which 1000 people died weekly of plague in London during an epidemic in 1563-64. The last case reported in England was in 1679, and during the 76 years between 1603-79 plague was absent from the death returns on four occasions only, in 1629, 1633, 1635, and 1670; the total mortality being 188,571. From toward the end of the seventeenth century the disease showed a tendency to retrocede eastward, and although during this and the eighteenth centuries it was prevalent in France and other parts of Europe, the areas affected were much diminished. In this nineteenth century there have been more or less severe outbreaks over limited areas of Europe and in Persia; the last appearance in Europe being in the Russian epidemic of 1878-79. This will show the lengthy period over which the disease will manifest itself, and no subsequent history is calculated to lead us to suppose we can get rid of the disease after one outbreak, in other words "stamp out" the plague, a phrase which has often been in some men's mouths in India since 1896. Take, again, the outbreak in Ahmedabad, in 1618, said to have started in the Punjab in 1611, and lasting for eight years; again starting in 1812 in Cutch and spreading to Ahmedabad, devastating large tracts of country till 1821; the next outbreak at Pali, in 1836, lasted till 1838, killing 60,000 people. The first accounts of trustworthy details of plague in India refer to this epidemic in Cutch, which broke out at a time succeeding a severe famine.

The origin of the disease is a mystery, but the origin of other well understood diseases, *e.g.*, syphilis, is also unknown. The conditions favoring the persistence of plague when once it is introduced present a uniform consistency, and there is no material deviation in the observations of authorities as to what they are, although as such conditions existed before the disease manifested itself, and continued after its cessation, they help us to no solution as to the origin of the disease. The conditions are want of light and air, overcrowding, and poverty, and the very often accompanying personal and general surrounding filth. In exemplification I may quote one remark about the people of Dholera, a locality affected during the above-mentioned epidemic in Cutch: "They wear large quantities of clothes which are not changed till they drop off rotten with filth. The filth is ingrained in their skins." The disease as regards one point particularly is like typhus, in that it attacks people living on the ground floor of a house much more than, and in decreasing ratio, those living in the higher ones. This fact was observed in Bombay in the epidemic 1896-97, but may be partly accounted for by more over-crowding on the ground floors. An instance may be given from the Cutch epidemic. Among the places to which it spread was Moroi. A medical officer who reported on the outbreak says that the Thakur's palace, containing about 100 people, escaped completely. It was a large well-aired place, elevated above the other parts of the town. Equal immunity was enjoyed by a small village situated on the opposite side of the river less than a quarter of a mile away on a very high and exposed situation, although there was daily and hourly communication between the village and the infected town.

There is nothing in the history of plague to show that climatic conditions have any effect upon its progress or cessation. It has prevailed in hot, cold, dry, and wet seasons, and any changes in the prevalence of the disease at certain seasonal variations seem to be purely coincidental, and determined by the natural course of epidemics, ascent, height, and descent. To sum the case up briefly, after a study of the conditions under which plague has prevailed, we are not advanced beyond the knowledge that other infec-

tious diseases, such as typhus, have prevailed under similar conditions, poor, ill-fed, dirty populations living in crowds with absence of light and air. Improvement in such conditions in Europe, improvements which have taken generations to effect, may reasonably be said to have caused the retrocession of plague thence.

Mode of Transmission.—Although the origin of infection may defy elucidation, once the disease has manifested its presence opportunities occur for observing the method of its transmission from person to person, and place to place. More or less definite modes of spread have been determined for various of the infective fevers. Allowing that each infective disease has a poisonous entity outside the body, it is wide of the purpose of this article to discuss the mode of entry of such into the body, as we cannot expect to know of plague yet what we know of none of the infectious diseases, that is, how the poison enters the system. One point I may just refer to, as it seems proved in some men's minds. The preponderance of femoral buboes in plague is supposed to show that the infection took place through abrasions or cuts on the feet; personally I have not been able to find such abrasions, and the only cases in which there was a solution of continuity of the skin affording a possible channel of entry, the bubo in the femoral region was on the opposite side. In one hospital in Bombay in 1897 the inguinal buboes on the left side were more frequent than the femoral on the same side. The next most frequent sites for the buboes are the inguinal axillary regions. The latter might be accounted for by infection from the hands; but I take the question to be entirely one of "might be." The same order of frequency as to the position of buboes is being observed in the Oporto outbreak at the present time, and it is not stated to be the case that the population all go bare-footed.

To return to the subject of the means of transmission. I think here we cannot separate sharply contagion and infection, and I propose including the former in the latter term. The first point to consider is the communication of the disease from the affected to those in immediate contact. It is almost impossible to judge of the extent to which this may take place during the height of an epidemic, as in a large freely intermingling population one cannot trace the direct connection, and many persons may become infected from a common source apart from any contact with those suffering from the disease. But in the early stages there are greater facilities for proving this mode of transmission. There is clear evidence as to the circumstances under which such transmission will and will not prevail. To take the former case first, ten people assembled every night at a house in Calcutta for gunja smoking. On March 16, 1899, A fell ill with plague, and died on the 20th. (For simplification I will use alphabetical letters.) On March 22d B who lived elsewhere became ill and died the 26th. C and D after a week's illness died on March 28th and 29th, and E died on the 30th, all elsewhere. F fell ill at his house elsewhere, on the 27th and died March 28th, and F's wife was taken on March 30th and died April 2d. They had two sons who, after the mother's death, left the house and went to live elsewhere, and one of them developed plague on April 5th and died on the 7th. This case, details of which were obtained after great trouble by Dr. Justice, in charge of the district, shows how infection can be carried by human beings; except in the cases noted, no spread could be traced from the infected people; although such may have been the case. The facts related, while distinctly showing that the infection can be carried from man to man, also exemplifies the comparatively small part such a method plays. Opinions may differ as to the extent the disease is spread by direct personal transmission, under the conditions of dirt, and over-crowding in ill-lighted and ill-ventilated habitations. French physicians who studied an epidemic in Egypt in the early part of this century declared against the disease being contagious. However this may be, there has long been an unanimous opinion that under conditions of light and air, plague infection is at a minimum. Going back to the plague in Pali, in 1836, Dr. Rennie, in his report, says: "I feel no hesitation in professing my belief that a man in sound health, provided he continue to breathe pure air, might safely keep his hand a whole day in contact with any one suffering from the Pali fever; but, if he sat within the same hut and inhaled the same tainted atmosphere half the time, he would probably be seized with similar illness. None of the medical officers or even native assistants, who handled patients affected with the Pali disease and felt their pulse for days and weeks have suffered."

To give instances in later times, in a plague hospital in Bombay, in 1897, of about 400 people who visited patients and in some instances remained constantly with them, not one contracted plague; and I have known a relative to sit on a bed with her arms round the patient for hours without becoming infected. Hospital attendants have been affected, but in a very small proportion. When one considers how a hospital must literally reek with infection, it is not surprising that some individuals, constantly breathing the air for weeks and months together, and in contact with various secretions, should contract the disease, especially if the health was impaired, as has been the case in the instances where European medical men have contracted plague in India and died. Every plague hospital displays the same immunity of visitors, relatives in constant attendance, and the hospital staff. Another point bearing on the same subject is that persons removed to a segregation camp from any infected locality cease to suffer from the disease. In the camp contiguous to the Plague Hospital at Bangalore, of which I had charge in 1898-99, there were 1598 people admitted of whom 51 developed plague, and the large majority of those in the first day after segregation, having evidently been infected

on admission. These people took the same clothes to the camp as they wore at home. It is needless to multiply instances. This is sufficient to allow us to make one positive assertion about the plague, *i.e.*, that the source of infection is deprived of virulence by exposure to light and air and, moreover, kindly lends itself very easily to such modifying influences.

We are naturally led now to the next step in the causation of infection, *viz.*, fomites. I will give two instances which bear on this. One is related by Hirsch as having occurred at Wetljanka in 1878, 1879. All the inhabitants of a certain house died, and two months after a box of clothing, which had not been touched previously, was sent to another house, the epidemic having disappeared. A girl took some of the clothing and set to work on it, and four days later she developed plague. One other instance occurred in 1897 during the Bombay epidemic. A vessel embarked a crew at Bombay on the 20th of August and arrived in the Thames on September the 11th. There were between 300 and 400 passengers on board, and no suspicion of plague had arisen. On the 26th or 27th of September one of the Goanese stewards became ill and died on October 3d. Another steward who slept in the same cabin as the first mentioned was also taken ill about the 26th and died on September the 27th. Both cases were plague, and the infection was traced to a bundle of clothes which had remained unopened until the end of the voyage. In connection with this, it will be interesting to note some laboratory experiments as to the vitality of the plague bacillus, as such experiments tend to bear out what has been observed as to the lessened danger of infection when in the presence of light and air. The German Plague Commission, who went to Bombay report that "outside of the body of man or of the bodies of certain animals the plague bacillus shows a notable tendency to perish. Pure cultivations of the plague bacillus from different sources and of different ages in fluid or on solid media were found to be quite dead after 15 minutes continuous exposure to a heat of 70° C. When the heat was 80° C. five minutes were enough for sterilization. A cultivation suspended in water, when examined immediately after exposure to 100° C. was found to contain no living bacilli. Material containing plague bacilli was placed in different ways upon linen, wool, silk stuff, and also upon threads, gauze, filter paper, pieces of glass, earth, etc., kept in different conditions, and tested from time to time as to its infectiousness. The life of the bacilli under these circumstances was at most eight to ten days, and often only two to five days. The infectiousness of bacilli on the dried skin of two mice that had died of plague was extinguished in the one case on the fourth, and in the other on the sixth day. The German Plague Commission also found that corrosive sublimate 1-1000 killed the bacilli at once; carbolic acid 1-1000 in ten minutes. The bacillus is also sensitive to mineral acids, being destroyed in five minutes by pure sulphuric acid diluted to 1-2000. Yet at Poona it has been reported that disinfection and evacuation of houses for ten days only was quite useless, and as the people returned they were attacked with plague within a few days. The weak point of these and similar experiments is that the bacillus is placed and observed under artificial and manufactured conditions, which are not safe for certain guides as to the vitality of infection under natural conditions; of which latter, except as noted previously, we are ignorant. The constant recrudescences of plague in the Himalayan regions of Kumaon and Garhwal point to the infection being kept up in fomites. Articles of merchandise and foodstuffs must be noted apart from fomites, as there is no case on record where plague has been introduced from one country to another, or from place to place in an infected country by such means; suppositions that such may have been the case have been mooted, but there are no facts on record to make them reasonable, at all events during modern times.

The third step in this direction concerns the question of infection from animals. I will confine myself to rats, one of the very limited class liable to plague. I cannot disabuse my mind of the conviction that the spread of infection by rats, even from house to house or street to street, has been magnified out of all proportion by an undue concentration of thought on that limited sphere of the subject. The fact is that in ancient and modern times, an outbreak of plague in human beings has been preceded in many instances by a large mortality among rats. How do the rats become infected? No one knows. There are nothing but theories to be found; for instance, when plague existed at Hardwar, on the Ganges, in 1897, unusual mortality among rats took place at Kankhal, about a mile distant. It is not suggested that infected rats walked that mile from Hardwar, but that the ones resident at Kankhal got infected by food (grain, etc.) taken to Kankhal. Now, what happened; the disease in the rats ended (or the rats all came to an end) and disinfection was carried out where rats had died, and sugar, grain, etc., exposed to the sun for eight hours. This was in the middle of June, 1897, and the last case at Hardwar was reported on the 8th of June. No cases were reported then at Kankhal, and all seems to have gone well until September, communication meantime taking place between Bombay and Kankhal. In the first week in September cases of acute illness with rapid death were occurring, but plague was not declared until the 16th and then became epidemic. I think this case requires no other explanation than human transmission. I can find no instances of infection being carried any distance by rats, and although it is supposed that rats which have died of plague may be carried in grain, it is, on the other hand, stated that the power to infect very soon becomes destroyed in dead bodies. To quote two authorities in support of my opinion, Dr. Bitter and Dr. Rogers, of the Egyptian

Plague Commission, hold the view that rats are of very minor importance in spreading the disease.

Treatment.—The part of the subject of most absorbing interest to the practical physician is the treatment of the disease, or, rather, the treatment of the patient suffering from the disease, as individual cases will present in this, as in all other diseases, symptoms indicating remedies having no obvious relation at first sight to the nomenclature of the complaint. Patients, not diseases, call for treatment. At the same time, certain classes of remedies are adapted to the majority of patients suffering from the more prominent manifestations of the totality of the symptoms, defined by the nomenclature of diseases. I will consider the experience of plague treatment under three headings and confine myself to drug medication, as consideration of vis-medicatrix nature, which is too obviously a minus quantity in this disease, and dieting with general hygienic measures, etc., carry us no way at all. (1) Treatment by what I will call ordinary traditional medicine. (2) Treatment by serum as practised by Dr. Yersin. (3) Treatment, introduced by myself, by snake venoms.

(1) The records under this heading display a collection of compound prescriptions with from three to six drugs given systematically, with various prescriptions for individual symptoms; in short, a routine method of symptom treatment, based on, well, I suppose, orthodoxy! I will take some hospital records in order, and call them A, etc.

A reports: "As regards the effect of medicine, it cannot be stated with satisfaction that we possess any standard remedies of certainty. What might seemingly cure one patient is ineffective in another of the same type (because the patients want treating, not the disease. H. E. D.), and it is questionable whether the successes shown are not wholly due to scientific nursing and hygienic surroundings of a superior nature." The following was the drug treatment in this hospital under which one patient recovered, but it is reported that several others similarly treated derived no benefit and died. Magn. sulph. ʒvi was given to begin with; then every three hours:

℞ Sodii salicyl. ..... grs. v
Liq. hyd. perchlor. ..... ʒss
Sp. octheris Nit. ..... ʒss
Tinct. digit. ..... ♏ v
Rum ..... ʒss
Water ..... ʒiss.

"The object of the above prescription was, first, that the salicylate of soda acted as a diaphoretic and antipyretic; digitalis was inserted both as a cardiac tonic and to counteract any depressing effect which the salicylate might cause. The nitrate was also given to encourage the secretions, and rum for its stimulating qualities. The mercury was added for its alterative and antiseptic qualities under the idea that some poison would be neutralized."

I quote this in full, not to criticise the author of it, but to let it stand as its own comment on a system of medicine which is no practical improvement on Galen's instructions as to determining whether a disease is hot or cold and then administrating a cold or hot drug. We, in this nineteenth century, instead of hot and cold diseases, have ideas as to poisons requiring neutralizing, an idea somewhat akin to the doctrines of the ancient Dogmatists, and we call drugs, instead of hot and cold, alterative, tonic, eliminative, stimulating, etc., classing many drugs with very distinctive actions on the human body, under a theoretical and artificial nomenclature.

Another stock prescription largely given was as follows:

Liq. strych. ..... ♏ iii
Carbolic acid ..... ♏ ii
Tinct. iodine ..... ♏ iv
Tinct. digitalis ..... ♏ v
Aqua ..... ʒi
Every three hours.

In addition there was the usual prescription of morphine at bed-time, Dover's powder for diarrhea and, in short, the indiscriminate symptom treatment of orthodox medicine. I need not multiply these prescriptions, but will give results of various hospitals.

In the above-mentioned hospital the mortality was 60 per cent. Total number admitted, 374. In B hospital, total admissions, 304; mortality, 64 per cent. In C hospital, 86 admitted; mortality, 72 per cent. In D hospital, admissions, 107; mortality, 68 per cent.

I have only mentioned hospitals that were under European officers. All the private and caste hospitals tell the same doleful tale, although treating a smaller number of cases; the mortality being from 60 per cent. to 90 per cent. These figures include all cases admitted, many of them in a moribund condition, and some dying in 24 and 48 hours. There is no other reliable way of judging the effects of any treatment; selection of cases or omission of those dying within a certain time are fallacious and misleading; and treatment of an acute febrile disease which fails to alleviate the tendency to death in 48 hours must be said to have failed. It will be instructive to quote two more extracts regarding two of the above hospitals, as showing that a theory of the nature of a disease and of the action of remedies does not help us.

"As a special mode of treatment liq. hydrarg. perchlor. was resorted to from a conviction of the value of such a powerful disinfectant in specific disease, and the likelihood of its being useful as an intestinal disinfectant and bactericide. The general result of the hospital treatment may be attributed to this mode of medication (with remedies for prominent symptoms and complications), and gave 69 per cent. of recoveries, excluding cases moribund on admission, and those treated by Yersin and Haffkine . . . . but it is only right to state that many cases treated

early and vigorously with this drug died, after perhaps temporary benefit and prolonged life."

"In one remarkable case which died six days after admission from double bronchopneumonia, and under full doses of mercury, the German Plague Commission found plague bacilli on three different days in the blood-cultures, but the day before death and at the post-mortem not a single plague bacillus could be demonstrated in the blood or any of the organs. Their conviction was that the patient died from the severe complication,[1] and had his vitality been greater and no complication supervened, he would certainly not have died of plague, all the bacilli being destroyed." No doubt comments on this will suggest themselves, especially to those of a humorous turn of mind; personally I will only say it reminds me of the story of the Frenchman who tried the experiment of keeping his horse alive without food, and was succeeding nicely when the animal died. The other and last note on this subject which I shall give says that "as no specific has hitherto been discovered for the plague, the treatment resolves itself into the carrying out of the general principles of medicine as applied to the treatment of symptoms arising in the course of the disease. The stimulant method and the administration of liq. hyd. perchlor. have both been given the full est trial, and both have proved equally inefficacious in either controlling or checking the disease."

(2) Dr. Yersin has been chiefly associated with the antitoxin serum treatment of plague, and as there are fuller records of the use of his serum than that of any others of a similar kind, I shall only deal with his, other serums having also the same dismal tale to tell. The antitoxic preparation was obtained from the horse, the animal being inoculated with plague virus, until lethal doses were inoperative. The blood serum then injected into another animal "effectively hinders the reproduction of the bacilli and the formation of toxins." Before going further I must say that in this attempt at treating plague there was a step in the direction toward which all scientific and beneficial therapeutics is now treading—*the single remedy*. I will give the hospital experiences of the treatment, and Dr. Yersin's own tabulated statement.

The report of A hospital says: "Professor Yersin visited the hospital on two separate occasions and declined to use his curative lymph. The many patients present, were, in his opinion, unsuitable to his purpose or otherwise far advanced in the disease."

In B hospital, 23 cases of plague were treated; but there is no mention as to their being selected, which vitiates results. Of these 13 died and 10 recovered, giving a mortality of 56 per cent. "Delirium seemed to be lessened by the serum. No improvement in the general condition of the patients could be seen, and the inflamed glands were certainly not favorably affected." In one case, serum having the guarantee of Dr. Roux and Dr. Yersin was used in a case not of severe type, and, according to Dr. Yersin, a suitable one for curative serum treatment. "Fresh buboes appeared, the primary ones became larger, more inflamed with increased surrounding edema, and the little patient died. This child, aged four years, was injected 42 hours from the initial sign, with a full dose of 40 c.c." In C hospital 4 cases were treated, the cases being selected and one being a doubtful case of plague. The other three died, and it was reported that the injection caused intense local discomfort, and "when two of the patients were conscious they dreaded a repetition of the process." In D hospital 4 cases were treated and 2 died.

When Dr. Yersin first went to Bombay he treated cases in all parts of the city and his results could not be compared by others, and he was asked to confine his treatment to the hospitals; the result of which is shown above. A statement he himself submitted to the Plague Committee gives:

17 cases treated first day of illness, mortality 12 per cent.
17 cases treated second day of illness, mortality 35 per cent.
12 cases treated third day of illness, mortality 50 per cent.
3 cases treated fourth day of illness, mortality 66 per cent.
1 case treated fifth day of illness, mortality 34 per cent.
Total of 50 cases, 34 per cent. mortality.

Before closing this part of the subject I cannot refrain from emphatically protesting against a system which has been in vogue when experiments with these serums have been made; and that is, having control cases. I think such an idea discreditable to any members of our profession who propose it. If any treatment offers any ground of hope of being successful, every patient should be given the chance of his life, and treating one case while leaving an alternate one, to watch if he will recover or die, is perilously near trying to improve medicine by murder. This may seem strong language; I intend it to be. If the Almighty has left us so helplessly in the dark as to treating the pains of the highest of His creation with the means He has given to our hands in the shape of medicinal plants, etc., rather than have recourse to such an unjustifiable system of playing with human life, let us renounce the practice of the profession until light be shed. Happily, such need not be, nor are we without a guide to treatment; but I must be content here to enter a protest against such counter-control experiments.

(3) The past history of the treatment of plague shows the use of every class of drug in the pharmacopoeia, tonics, cardiac and nervine stimulants, antiseptics, anodynes, antipyretics, diaphoretics, eliminative, et. id. *genus omne;* members of one class administrated with members of another class, and the result has been beneficially nil. The profession displays a wonderful consensus of opinion as to this. I venture to include my own treatment in considering this subject, because, like others, I have also my convictions, and my conviction about this is that the method of treatment I started in India offers

[1] This severe complication (!) is a very common and essential symptom, and an early manifested one of the clinical course of plague. H. E. D.

a better hope of success than anything of which we have present experience. I was influenced largely in volunteering for plague duty, when officers of my service were called for, by the conviction that means existed for reducing the awful death-rate. The limits of this article preclude my entering into full details, but I may say that I applied the principle which guides us in treating any disease, a principle which is now daily becoming wider spread, with consequent benefit to humanity. There is an acute disease, killing often with fulminating rapidity and clearly requiring a rapidly acting remedy; a septicemic disease, with early marked manifestations in the central nervous system. What remedies are indicated? It is becoming daily, as I said, more and more apparent that a remedy for any disease is one which acts on the same tissues as are affected by the disease. Trying to differentiate drug action *ab usu in morbis* has been tried for centuries, and has failed. Such action must be elicited by experiments on the healthy human body. The poisons which act on the same tissues as the plague poison, and, moreover, with startling rapidity, are the snake venoms. The success which had attended the treatment of yellow fever in America by the rattlesnake poison gave me a good precedent for my hope of similar success in plague. My opportunities in Bombay in 1897 were very limited, as the hospital in my district was put under a native hakim with whom I had orders not to interfere; it being hoped that letting the native have their own medical attendance would induce them voluntarily to go to hospital.

However, without treating on the susceptibilities of hakim or patients I managed to treat many of the latter, and the former took a great interest in the subject. The hospital was opened April 20, 1897, and I ceased connection with it about the middle of July. Fifty cases were treated of whom twenty-two died. The Government report says, "It is impossible, owing to the singular character of hakim's medicines, to give any account of the general treatment adopted. But the ratio of mortality is satisfactorily low, being 44 per cent. or nearly 9 per cent. below the mean rate of all hospitals." I used almost entirely here the Lachesis trigonocephalus administered by the mouth in the cases in which I used snake venoms. I must here make a further statement about this hospital, records of which are published to the end of 1897. Up to that time 158 cases were admitted, with the singularly low mortality of 31 per cent. I have reason to believe the treatment by snake venom was continued after I left, but, whether or no, I must give hakim Din Mahomed Bhagin credit for such a record.

(To be continued.)

Women Nurses in the Army.—The Chicago Medical Society recently endorsed a bill urging the appointment of women nurses in the medical department of the army.

EXPERIMENTAL RESEARCHES ON THE EFFECTS OF INCREASED BAROMETRIC PRESSURE AND OF FOREIGN BODIES IN THE PHARYNX, ESOPHAGUS, TRACHEA AND LARYNX.

By GEORGE W. CRILE, A.M., M.D.,
OF CLEVELAND, OHIO;
PROFESSOR OF CLINICAL SURGERY AND APPLIED ANATOMY, CLEVELAND COLLEGE OF PHYSICIANS AND SURGEONS; SURGEON TO ST. ALEXIS AND CLEVELAND GENERAL HOSPITALS.

(Continued from page 129.)

III. Foreign Bodies in the Trachea and the Larynx.

Preliminary Remarks.—In cases of foreign bodies in the respiratory tract there is often from the symptoms alone great difficulty in determining their location. It is difficult also to decide whether or not an operation is indicated and, if indicated, where this operation is to be performed. The number of futile attempts at finding foreign bodies, and the number of catastrophies that have followed such accidents, suggested the following research.

Protocols.— The following experiments were made with a view to ascertaining the comparative values of chloroform and ether in point of safety in operations involving the upper air-passages.

1. On a sixteen-pound mongrel, in a fair condition, under ether anesthesia, the following dissections were made: Both vagi were dissected free from the carotids throughout the length of the neck; then the superior laryngeals were dissected out from their origin in the vagi to their entrance into the box of the larynx; next the glossopharyngeal was dissected out from its exit from the cranial cavity to its terminals in the muscles; finally, the hypoglossal was similarly dissected, thus exposing these structures on both sides. During the dissections the animal breathed fairly well without requiring much attention to the ether anesthesia, which was administered by means of a tracheal tube to which a rubber tube and funnel were attached in which latter cotton-wool was thrust. Manipulations of these nerves, especially of the vagus and inferior laryngeal, interfered with the respiratory as well as the circulatory action. In no instance, however, was it necessary to supply artificial respiration.

2. Dissections under chloroform anesthesia were carried out as similar to the preceding as possible, occupying as nearly as possible the same length of time in their performance on a seventeen-pound bird-dog. During the anesthesia it was noted that the blood-pressure would sink whenever the respirations became slowed and that the pressure would recover itself upon removal of the anesthetic. Early in the experiment it was found necessary to maintain artificial respiration for a short period of time, and during the latter part of the dissection respirations became extremely shallow and weak. Manipulation of the superior laryngeal or the vagus

interfered with the respirations more markedly than in the preceding experiment.

3. The following experiment under ether anesthesia on a water-spaniel weighing twenty-four pounds was performed. The trachea and the laryux were both dissected free, the trachea severed at the cricoid junction, then the superior laryngeal was dissected out from its origin to its termination on both sides of the neck. A finger passed up within the larynx produced thereby an irritation in the area for inhibition. The superior laryngeals were stimulated by the faradic current, thus producing temporary arrest of respiration and complete inhibition of the heart's action. On cessation of the stimulation, both the cardiac and the respiratory actions were resumed. After this the animal was allowed to

Fig. 7.

Experiment on the removal of a laryngeal tube by means of external manipulation.—The upper tracing represents the respiration, the next the blood-pressure, below which are the signal and the time.

rest undisturbed with these structures exposed to the air. The respirations were decreased in amplitude and in frequency, but at no time ceased, excepting when some special irritation produced reflex inhibition.

4. A bull-terrier, weighing twenty-eight pounds, in fair condition, was subjected, under chloroform anesthesia, to as nearly as possible the same procedure as in the foregoing case, occupying about the same length of time, with the following result: The reflex inhibitions on both the respirations and the heart were, under chloroform anesthesia, comparatively more profound. During the dissection respirations were so shallow as to cause considerable cyanosis, and for a time artificial respirations were supplied. At the close of the experiments, when the animal was allowed to rest, the respiratory action was extremely feeble and the blood-pressure had fallen more than one-half from its original height.

5. The following experiments, under ether anesthesia, were performed on a mongrel cur, weighing eighteen pounds: The superior laryngeal nerves on both sides were exposed and subjected to stimulation by mechanical manipulation, producing thereby a reflex arrest of respiration. The faradic current was then applied, producing reflex inhibition of both the respiratory and the cardiac action. This was repeated twice on each side. The normal action was regained with a fair degree of readiness after cessation of the stimulation in each instance. Artificial respirations were not required.

6. On a healthy water-spaniel, weighing twenty-two pounds, during the technic of dissecting out the trachea and applying the tracheal apparatus for maintaining anesthesia under chloroform, respirations ceased and artificial respiration was supplied during a period of five minutes, after which very slow, voluntary efforts were noted, gradually increasing in amplitude and rapidity until an over-respiratory action and recovery occurred. On reducing the animal to surgical anesthesia again, a like result was observed. During the experiment, carried out as nearly as possible as in the preceding case, the respirations were very much slowed and quite shallow, so that it was difficult to obtain a good tracing. In these experiments the larynx was exposed to all kinds of rude manipulation, for the purpose of facilitating a comparison between the results under chloroform and under ether anesthesia.

7. This experiment and the following were performed for the purpose of determining whether or not traction on the trachea from the lungs upward, or from the larynx downward, or lifting the entire trachea forcibly out of its bed, caused an effect upon the blood-pressure and the respiration. The trachea of a healthy twenty-pound mongrel was freely exposed under ether anesthesia by bloodless dissection, and after securing a control tracing of the respiration and the blood-pressure, a hook was placed between the rings of the upper portion of the trachea. and the latter organ was pulled strongly upward from the lungs in the line of its own axis. This produced no effect upon the respiratory rhythm, but it caused a fall in blood-pressure, this fall taking the form of a rather sharply rounded curve, from which it quickly recovered. Then, repeating the same maneuver, like effects were produced. The line of traction was then reversed and the trachea dragged downward on the line of its own axis, producing a dragging upon the entire larynx and the pharynx. This was followed by a decided fall in the blood-pressure and a temporary slowing of respiration. This experiment was twice repeated, with like results, although in each subsequent repetition

the phenomena were not so marked as in the one immediately preceding. In dragging upward on the trachea, when the dragging was quickly applied, the fall in blood-pressure was correspondingly more abrupt, and suggested the probable action of mechanical causes interfering with the return circulation in the venous trunks which pass in such close anatomical relation to the trachea.

8. The animal, a fox-terrier, weighing twenty pounds, was subjected to experiments similar to those in the preceding case The phenomena attending upward traction on the trachea were practically the same as in the preceding case, except that there seemed to be some increase in the depth of respirations. On dragging down on the trachea the respirations were more decidedly slowed, and for a short period at the first dragging respirations were arrested. On raising the trachea with some force up out of its bed results similar to dragging down upon the trachea were produced.

9. Experiments, under ether anesthesia, similar to the preceding were performed on a forty-pound bull-dog with the same results, except that in dragging down forcibly upon the trachea there was a distinct inhibitory action upon the heart, whereby sweeping slow beats were executed during the period of most forcible traction. Raising the trachea up from its bed with considerable force produced similar symptoms, although less marked.

While the first six experiments involved the mere dissection and thorough stimulation of certain nerves, they confirm what has been very frequently observed in other experiments upon the respiratory tract, *viz.*, that animals under chloroform anesthesia are decidedly more liable to respiratory failure than animals under ether anesthesia. While it is recognized that it is very difficult to make satisfactory comparative observations, it has seemed that reflex inhibitory phenomena are more profound under chloroform than under ether anesthesia inasmuch as in other experimental work, not relating to this present object and purpose, similar observations have been made. These additional experiments have been made principally to test the effect of dissections upon and about the larynx and trachea, and involving the nerve trunks supplying this area.

The Physiologic Principles Involved.—The physiologic principles involved in this question are practically the same as those indicated under several other headings in this paper, namely, that no amount of irritation of the mucosa or structure of the trachea, even the cricoid portion of the larynx, is capable of producing any marked sudden effects upon either the circulation or the respiration.

Such an irritation, however, if applied to the middle or upper part of the larynx would cause most pronounced reflex inhibitory phenomena. The only reflex phenomena that a foreign body below the larynx could produce is that of coughing. While in the larynx not only coughing may be produced on slight irritation, but on greater irritation reflex arrest of respiration will occur, and on still greater irritation, in addition to the reflex arrest of respiration, there may be reflex arrest of the heart's action, causing thereby a collapse more or less profound. The symptoms of asphyxia from obstruction need never be mistaken for those of reflex inhibition from the laryngeal area.

In the case of asphyxia from obstruction, the respiratory as well as the circulatory activity will continue. The pulse will be strong and full and slow, until, finally, after from five to eight minutes, there will be intermissions, then irregular actions, then intermissions until the heart ceases in diastole. In reflex inhibition there is sudden collapse, with sudden cessation of respiratory action, and, if the circulatory action is also affected, there will be no arrest of the heart as sudden as the arrest of the respiration.

Differential Diagnosis of Tracheal and Laryngeal Lodgments.—A foreign body lodging in the trachea and not dislodged from the trachea during the attacks of coughing is incapable of producing any effect other than that indirectly produced by the powerful respiratory alterations in the act of coughing. If the foreign body is so large and the swelling so great as to completely obstruct the tube, the symptoms of asphxia, as above described, will appear. If, however, the foreign body is lodged in the larynx, there are likely to appear attacks of cyanosis, sudden in onset, during which the subject becomes cyanotic, greatly depressed—in short, passes into collapse—and, after a variable period, respirations are gradually resumed, the cyanosis disappears, and the heart again beats normally for that particular case.

A slight movement, a cough, or an attempt at examination, may precipitate such a collapse. Furthermore, supposing a foreign body to have been inspired into the trachea and during a violent fit of coughing to have been expelled from the trachea into the larynx, such reflex inhibition would most likely suddenly appear. If, then, a sudden collapse takes its onset in the middle of the latter part of a severe coughing spell, it may be assumed that that foreign body had not been in the larynx at the beginning of the coughing, but it was forced into the larynx by the powerful expiratory efforts.

Extraction of the Foreign Body.—In all cases of operative procedure to extract foreign bodies from the respiratory tract it seems a judicious precaution to inject a sufficient dosage of atropine to protect the heart against the reflex inhibitory impulses through the superior laryngeal nerve, so that, if respirations should fail, the circulation will be sufficiently guarded and the operation may be completed while artificial respirations are maintained. This is especially necessary in cases in which the diagnosis has been made of lodgment in the larynx.

In cases not so diagnosticated, however, there

is by no means a certainty that in the fits of coughing the foreign body will not be forced into the larynx before the technic can be completed. In cases in which it is practicable, a spray of cocaine or an intralaryngeal application of cocaine is of the greatest service in protecting the patient against sudden collapse. As has been amply proven, experimentally as well as clinically, the local application of cocaine upon the laryngeal mucosa, even with so weak a solution as one-half of one per cent., completely prevents the reflex inhibitory effect upon both the respiration and the heart, no matter to what extent the irritation of the larynx may be carried. In cases in which this preliminary preparation can be satisfactorily carried out, it would give an absolutely certain precaution against sudden collapse or death.

Technic of Operative Procedure.—In every case in which it is possible, local rather than general anesthesia should be employed. The principal reasons for this preference are the following: If the subject can be controlled, so that the operation may be performed under local anesthesia, there is less disturbance, less struggle, and, therefore, less opportunity for dislodging the foreign body; the patient may aid the surgeon in various ways in his attempt to recover the foreign body; and, finally, when the respiratory passages are so occluded as to require the action of extraordinary muscles of respiration it would be almost fatal to attempt a general anesthetic, because in this case the exchange of air can only be accomplished by the aid of the extraordinary muscles. A general anesthetic paralyses these extraordinary muscles of respiration, and, therefore, the burden of supplying air is thrown on the ordinary muscles of respiration, which are incapable of performing this function, and the patient necessarily dies of suffocation. The importance of recognizing these two factors in labored respiratory action, in view of the fact that one group of muscles is paralyzed by general anesthesia, cannot be over-estimated.

In the choice of local anesthesia cocaine is preferable to eucaine. The reasons for this preference are the following: Cocaine produces ischemia, while eucaine produces hyperemia. Inasmuch as hemorrhage, even slight, is of considerable significance in this operation, cocaine to that extent is preferable. The effect of cocaine is more prompt than that of eucaine, and, inasmuch as in this operation expedition is often urgently demanded, the operation may be more quickly performed under the more quickly-acting anesthetic, finally, the necessary dosage of ether, when properly used, is sufficient to endanger life. A one-tenth of one per cent. solution has been found of sufficient strength, in my experience, for inducing anesthesia. It might be well to point out here that after the skin incision has been made but few sensory nerve terminals will be encountered in the section through the subcutaneous tissue until the structures of the trachea or the larynx have been reached. It is necessary to pause here and inject a new line of the anesthetic. It is sometimes unnecessary to inject any anesthetic in the dissection between the skin and the surface of the respiratory tube. After making the incision into the respiratory tube it is advisable to apply cocaine or eucaine upon the mucosa by means of a swab or spray for a distance above and below the opening sufficient to protect the area of possible operative procedures.

It is especially important, if the larynx can be reached from the point of opening, to cocainize its interior. This having been done, sudden collapse and death are quite impossible. This statement may seem rather positive, but any one having seen the emphatic experimental results and having tried this technic clinically cannot say less. It matters not whether the operation is performed under general anesthesia or under local, this precaution should be taken inasmuch as it is true that, while general anesthesia protects the patient against pain, it does not prevent the reflex inhibition, so that cocainization serves precisely as important a purpose under general anesthesia as it does under local.

In the choice of general anesthetics the patient may be more quietly and readily reduced under chloroform than under ether, and the tendency to the secretion of mucus is less. In these respects chloroform is preferable to ether. In another very important respect ether is preferable to chloroform, namely, under chloroform anesthesia there is a decidedly greater tendency towards respiratory failure and reflex inhibitory phenomena than under ether anesthesia.

This observation on the comparative effect of chloroform and of ether is in full accord with work done by Gaskill and Shore, Leonard Hill and Waller, whose conclusions, based on a large number of experiments, show that chloroform exerts a much more toxic action upon the muscle-fibers of the heart than does ether, so that, in a given case of full chloroform anesthesia, it is probable that the heart muscle is more easily inhibited than under ether anesthesia, producing, as it does, less direct toxic action upon the heart muscle. On the whole, it would probably be best to reduce the patient to surgical anesthesia by means of chloroform, then continue with ether, unless ample precaution against collapse is made by local application of cocaine. Inasmuch as it is not the intention of this paper to deal with the general aspects of these questions, no comments will be made on other points in the technic or treatment.

It has been frequently observed that if the foreign body is not lodged high up in the respiratory tract it is likely to be found at the bifurcation or in one of the bronchi, most frequently the left. There is, it seems to me, an additional explanation for this fact aside from that usually made. It is readily demonstrable that the expiratory efforts of the respiratory apparatus are more powerful than the inspiratory. It is necessarily true that an inspiratory force exerted on

a foreign body cannot exceed that of the atmospheric pressure rushing from an area of higher pressure to that of a lower, that is to say, rushing into the chest during the formation of a partial vacuum therein. The expiratory force is limited only to the capacity of all the extraordinary muscles of respiration, which collectively include large groups of muscles, many of which are the strongest muscles of the body.

It has been shown by experimental physiologists that the expiratory groups of muscles are more powerful than the inspiratory. It follows, then, other things remaining the same, that a foreign body subjected to the play of these two factors acting in opposite directions, must find a lodgment toward the side of the one which is weakest. Now, when the foreign body has dropped down so low as to become engaged in one of the bronchial tubes, the force of the respiratory efforts is only partially applied to this lodgment of the foreign body because of the want of resistance in the free bronchial tube; while, if the foreign body were in the trachea, the entire force of the expiratory efforts would be directed against the foreign body, and so would likely drive it onward into the larynx. On purely theoretic grounds it would seem that if in a given case of lodgment of a foreign body in one bronchial tube, after a failure of respiratory efforts to dislodge it, the free bronchial tube were closed by an obturator quickly applied, so that the whole expiratory force might be brought to bear upon both bronchial tubes alike, thereby increasing to a great extent the expulsive force exerted upon the foreign body, such additional force might occasionally dislodge the foreign body that has resisted all other efforts. This, however, is a mere theoretic suggestion, not founded upon either direct experimental or clinical evidence.

In fixing the trachea with a hook, and, indeed, in any portion of the technic, it is of importance not to drag from above downward with too much force, else there may be produced an inhibitory effect upon the respiration, and, if the force be very severe, also upon the heart. This does not so much apply to traction from the lungs upward in line of the tracheal axis. Lifting the trachea out of its bed forcibly is objectionable for the same reason that dragging down too forcibly upon the trachea should be avoided.

SOME OF THE EUROPEAN SANATORIA FOR CONSUMPTIVES, AND THE FINAL AIMS OF PHTHISIOTHERAPY.[1]

By W. FREUDENTHAL, M.D.,
OF NEW YORK.

While abroad last summer I had occasion to visit many of the German sanatoria, and some of the Swiss, and I shall limit myself to-night to describing some of the *ideas* that prevail there.

Throughout Europe there is now being displayed an intense activity in the erection of sanatoria for consumptives, an activity heretofore unknown even there. This movement received a fresh impetus in Germany because of the Berlin Congress for Tuberculosis, held May 24-27, 1899, under the auspices of the Empress of Germany and some of the highest officials in that country.

Although it may not have been appropriate to discuss medical problems not at all settled by the profession in a lay society, as this Congress was, still two of the main leaders of that Congress, *viz.,* E. von Leyden and Bernhard Fränkel, deserve the greatest credit for stirring up the masses of the population to the recognition of the fact that something must be done for poor consumptives. How much can be achieved by the help of the laity has been shown in a small county of Westfalia, where, through the energy and perseverance of the "Landrath" Heydweiller, a sanatorium with one hundred beds has been built and is being managed and cared for by the county itself. Mr. Heydweiller, who, as I have said, is not a physician, kindly sent me his report on the sanatorium at Altena (Die Volksheilstätte des Kreises Altena. Paul Dalichow, Lüdenscheid), and I would recommend this booklet to every one interested in the question. He starts with the idea in view that it is the duty of the community, by erecting sanatoria, to care for consumptives in the same way as is done in general hospitals and other departments for the poor. Although his county consists of only 87,000 inhabitants, he succeeded in raising 400,000 marks, the greatest part of which was given by the community itself. When ninety beds are occupied, it is self-supporting.

There are but few other communities which have built sanatoria, as for example Berlin, at Malchow, with 96 beds, and Leipzig, with 60 beds. By far the majority, however, of these sanatoria have been built by private societies. The first one of these, in fact the first sanatorium for the poor, is that at Ruppertshain a. Taunus.

One cannot speak of the sanatoria in Germany without mentioning the oldest one, *viz.,* Brehmer's sanatorium at Görbersdorf. I personally knew Brehmer and can truly say that he deserves all the credit which he has been given, as they are his ideas which we have been following for the last twenty-five years or more. Görbersdorf is, indeed, the cradle of mountain spas, and of the hardening free-air treatment rationally combined with hydrotherapeutic and other measures.

Dr. Hermann Brehmer founded his sanatorium at Görbersdorf in 1854. After his death, in 1889, there were several capable men at the head of the institution, Professor Kobert, Dr. Felix Wolff and others; but they all left and a rumor spread last summer that there was no physician-in-chief in charge of the sanatorium. Therefore I did not visit it at all. I hear that Dr. Schlössing at present occupies that position.

In 1875 Dr. Römpler opened a sanatorium at

[1] Read before the Medical Association of The Greater City of New York, December 11, 1899.

Görbersdorf, which still enjoys a good reputation.

One of Brehmer's former patients and assistants, and now the leading man in phthisiotherapy in Germany, is Dettweiler. A Frankfort society started for him in 1874 the well-known sanatorium of Falkenstein a. Taunus. Dettweiler is still connected with this institution as consultant. As he is the most prominent man since the death of Dr. Brehmer, and has many pupils even in the United States, I shall deal with his sanatorium at length. I shall omit describing the institutions and surroundings, as this has been done often enough, as for example by Dr. Knopf.[1]

As you all know, Dettweiler lays the greatest stress on the rest cure in the open air, and he has halls and pavilions built with comfortable chairs in them so that the patients may lie in them for hours every day. There are several small halls which can be turned like carousals, according to the direction of the wind, and here also are comfortable chairs, or rather sofas, for each patient. Such *"liegehallen"* (reclining halls) are now to be found in almost every sanatorium in Germany.

It is claimed that this open air rest cure brings the patient more in contact with the open air, gets him hardened and accustomed to fresh air so that he is enabled to lie outdoors for hours, even in cold weather, covered with blankets and furs, thus being hardened against catching cold and the inclemencies of the weather.

Brehmer, on the contrary, did not consider it correct to have the patient breathe the fresh air in reclining halls built for that purpose. He believed rather that it was much more to their advantage to lie temporarily in their rooms with open windows, or on the balconies adjoining them, because, critically considered, a reclining hall is nothing but a common room, overcrowded with patients, from which the fourth wall is missing. I never saw the truth of this statement so strikingly verified as at Ruppertshain, which is very near Falkenstein and erected by the same Frankfort society, but for the poor only. While at Falkenstein the patients were seen lying on their chairs in different parts of the park, at Ruppertshain all had to lie in the common hall packed together as closely as possible; in fact, when I entered that hall the air was really bad. It was noticeable to the sense of smell and surely not to be inhaled by invalids. If anything, this hall, sanctioned by many of the most modern scientists, reminded me of an idealized New York sweatshop. It is just this crowding which we have to avoid in order to get good air for the patient.

And now, imagine such a hall upon a warm summer's day, protected against every little breeze, filled with patients who have to lie for hours on their chairs, and you will have the same impression that I had, *viz.*, that this was not the correct treatment for consumptives.

But, aside from the bad air, there is another factor that speaks against these halls, *i.e.*, the inactivity of the patient. There can be no doubt that for some people, who in their struggle for life have overworked themselves and overtaxed their physical strength, a rest cure of a few weeks' duration can only be beneficial. Further the rest cure has decided attraction and charm, as Dr. Felix Wolff correctly remarks, when the patient takes it as a pleasant change after having performed all the exercises prescribed for him. But for the great mass of people who do not exercise, this cure is absolutely injurious. Here I am always reminded of Weir Mitchell's rest cure. This has done good in a great many cases; but to my conviction it has done harm in a great many more, *viz.*, when exhibited in an unsuitable condition. It is the same with consumptives.

Now, we must not forget that the less muscular work one does the less albumin is lost from the system; conversely, the more work done, the more albumin lost. We know that this is most marked in climbing, less in walking, still less in sitting, and least of all in lying. When, therefore, we have a patient suffering from consumption, we should conclude, according to Professor Cornet,[1] that all movements of the muscles should be limited to the least possible degree. Besides, through the toxines, the heart is also affected and by increased labor it might more readily give out. This is all very true, but by rational work in the open air, of which I shall speak later on, the appetite is increased largely and a tonic effect produced which is beneficial to all the functions of the human system. We lose albumin, but we gain more by the increase of nourishment which the patient takes. That overstraining of the heart is of detrimental effect, has been seen often enough, and only lately Turban reported a case of a man, fifty-four years of age, who, contrary to orders, took part in a skating race on the ice until he was exhausted. Myocarditis was the consequence. But such accidents can easily be prevented if we go to work in a rational manner.

The tuberculous patient needs, as is well recognized, a change in his whole mode of living. He acquired the disease by his occupation, and he must, therefore, change his habits entirely. Take for example a bookkeeper or a tailor, who has been sitting all the year round and doing his one-sided muscular work, and let him sit in a chair again and you will only make him worse. Such people need general exercise for their muscles, and the more systematic it can be given to them, the better for them. A letter-carrier having acquired consumption would not be advised to walk all day. He might need a rest, and I would surely give him other gymnastic exercises than walking, unless that were specially indicated.

An entire change of the patient's occupation is an absolute necessity for the success of the treatment, nor can this fact be stated too frequently, nor emphasized too strongly. Only this will give him the stimulus for his nutrition, thus improving his whole organism and enhancing his diminished vitality. It is because of this that we can not insist that all patients must have a rest cure,

[1] S. A. Knopf, Pulmonary Tuberculosis, Philadelphia: 1899.

[1] Professor Cornet, Die Tuberkulose, Wien, 1899.

or all patients must climb hills; no, this patient does this work, and that patient does just the contrary, both according to their previous habits of life, and they will both get well.

There is another point that has not been brought out so far as I know in this connection, *viz.*, the trophoneurotic condition of the consumptive. I am of the opinion, which already has been ventilated by Nauss, Strebel of Munich and others, that consumption in the first instance is a trophic-neurotic affection of a general and local nature. It is only later that an invasion of the tubercle bacilli takes place. Nauss believes that the seat of this neurotic affection lies in the medulla oblongata with special implication of the vagus nuclei. Thomas J. Mays [1] of Philadelphia is convinced that phthisis is alone due to an affection of the vagi. He goes so far as to inject 7 minims of a 2½ per cent. solution of pure silver nitrate over the course of these nerves. I have not risked doing that as yet, especially because I am not convinced of the correctness of Dr. May's theories. As Strebel [2] says, only the trophic fibers are affected, while the pulmonary branches of the vagus carry motor, sensory and centripetal and centrifugal vasomotor fibers also. Strebel does not believe, and I agree with him there, that the trophic fibers of the vagus alone are affected, but that the nerve takes part in the general trophic insufficiency of the consumptive; that secondarily, perhaps, degenerations in the vagus and medulla may be seen is very plausible, but the conclusions on this question are as yet not decisive. The causes for this general trophoneurotic affection are manifold, but this is not the place to discuss them; yet it is certain that such an insufficiency exists.

I was reminded of this fact only a few weeks ago when Dr. Wm. H. Thomson, in the discussion on the initial symptoms of phthisis, described in an excellent manner the emaciation due to consumption and its differential diagnosis from other forms of emaciation. I can give here only a few of Dr. Thomson's symptoms, *viz.*: The bones are flattened in a certain way and thin; the muscles elongated and flabby; the chin is markedly protruding when the patient is seen sideways, etc. If to this general trophic paresis is added the local affection, then the soil is prepared for the specific infection with tuberculosis and a general infection soon takes place. Now, we ought to try to overcome this trophoneurosis from the very start. A change of surroundings, different and better nourishment and the open air rest cure will surely help many patients, but not the majority. A trophoneurotic patient must not only be well nourished and have plenty of fresh air, but he must be occupied as well. This enforced rest for hours every day is apt to make anybody nervous, besides having other detrimental factors. For example, to have a young man lie on a verandah for days and weeks next to a young woman can surely not have a quieting effect on the nerves. This is what the owner of one of the best private sanatoria in Switzerland told me himself, and he is a believer in the rest cure. There are more reasons which could be mentioned against the long-continued rest, which I will, however, refrain from discussing.

Now to overcome all this, we must give the patient some occupation. Here lies the difficulty. But since this has been overcome in another branch of medicine—neurology—we can overcome it here also. It was a long time before neurologists recognized the great value of systematic occupation for their patients. I need only remind you here of Möbius, Wildermuth and others. The principal fighter in this field is a layman, Mr. A. Grohmann of Zürich,[1] who has published an ingenious little book on the technic and psychology in the occupation of nervous patients. He started an institution for this purpose at Zürich, with the help of Professor Forel, and deserves the greatest credit for his unfailing energy.

The way he defines the influence on the patient of work and of having accomplished something, the good and bad influence of one patient on the other, all this ought to be read in his book and can be applied to a certain degree to our phthisical patients, too.

As the main occupation he recommends agricultural work, then gardening, carpentering, and a few more. We could, somebody might say, achieve all this by rational gymnastics, but the difference in the influence between the two on the mind of the patient is as day is to night. When the patient knows that he has to plant flowers to-day, and to-morrow he has to shovel snow, he feels that his life is not worthless. When he sees the flowers blossom which he himself has planted, he experiences a satisfaction and pride that is better than any medicine we can give him. Therefore I wish to emphasize my conviction that instead of the rest cure, *I am in favor of a working cure.* Let the patient work and feel happy; that is the first step towards improvement.

I am aware how difficult this task is but I feel confident it can be done and it must be done. I know many institutions here and abroad where the patients do not know what to do to prevent ennui. One fixes general rules; take a walk; eat a little bit more, do this and do that occasionally, etc. While this is advised by many physicians, the tendency of the modern view is in a different direction, *viz.*, to keep the patient busy. One of the pioneers in this respect is Dr. Turban,[2] at Davos (Switzerland). He has made it a rule to instruct the patient that he has to get up at a certain time, has to take the rest cure at such an hour, has to walk at a certain time and so on. In this way he frees the patient of his *bête noire*—the lack of something to do and his helplessness—and the consequence is, as Dr. Turban told me

[1] Thomas J. Mays; "The Hypodermic Injection of Silver Nitrate," etc. Boston Medical and Surgical Journal, Vol. 140, No. 6, 1899.
[2] H. Strebel; "Die Tuberkulose und ihre Beziehungen zum Licht," Archiv für Lichttherapie, p. 41, etc., November, 1899.

personally, that he who does not come to the institution a neurasthenic will certainly not become one there. He has laid down his views in his book, which shows great practical experience and knowledge. This plan is also carried out by others similarly to the method employed in Dr. Turban's sanatorium. Although this is to be regarded as a great step in advance, I must repeat that it is still not quite the correct thing to do, for even here the patient sleeps nine hours, takes his rest cure for seven hours more, which makes sixteen hours out of the twenty-four, and the remainder of the day is divided between taking his several meals, etc. The days and the weeks may pass by quickly in this way, but a great deal of time is lost which could have been used for strengthening the heart and improving the trophoneurotic condition of the patient.

The following are the rules for the day laid down by Dr. Turban for an incipient case: 7 A.M., rising; 7:30 A.M., first breakfast, milk, coffee, bread, butter, honey; 8 A.M. douche; 8:15-9:15 A.M., mountain climbing with intervals of resting; 9:45-10:30 A.M., rest cure; 10:30-11 A.M., second breakfast, 1/2 liter of milk and bread and butter; 11-12 A.M., walking on a level, with resting; 12-1 P.M., rest cure; 1-2 P.M., dinner, soup, fish, meat and vegetables, roast with salad or compot, dessert, 1/4-1/2 bottle of wine; 2-2:30 P.M., standing and sitting in the open air; 2:30-4 P.M., rest cure; 4-4:30 P.M., 1 cup of milk coffee, 1/4 liter milk with rolls; 4-30-6 P.M., walking on a level; 6-7 P.M., rest cure; 7-7:45 P.M., supper, consisting of soup, warm meat with vegetables, cold meat with butter, compot and 1/2 bottle of beer; 8-9:30 P.M., rest cure; 10 P.M., retiring.

In cold or bad weather when sitting in the open air is impossible, the time for walking is shortened and accordingly the time for repose lengthened. For patients with fever, etc., the system is changed, and especially the rest cure prolonged. Naturally all these rules are subject to modifications to meet the requirements of special cases, and it was Turban, if I am not mistaken, who first introduced this exact division of the day for each individual.

Dr. Lucius Spengler, also at Davos, gives the following rules for a strong patient without fever: 6:30 A.M., a glass of milk; 7-7:30 A.M., rising; 7:30-8 A.M., breakfast; 8-9 A.M., walking; 9-11 A.M., reclining; 11-11:30 A.M., walking; 11:30 A.M.-12:30 P.M., reclining; 12:30-1:30 P.M., dinner; 1:30-2 P.M., sitting or walking; 2-4 P.M., reclining; 4-4:30 P.M., a glass of milk; 4:30-5:30 P.M., walking; 5:30-6:30 P.M., reclining, correspondence, etc.; 6:30-7:30 P.M., supper; 7:30-8 P.M., walking; 8-9 P.M., reclining; 10 P.M., retiring.

Of course these rules also are changed according to the condition of the patient. But we see from the tables how little work the patients are allowed to do, and I must say that to rest for about seven hours a day—sitting is resting, too—and sleep in bed for nine or ten hours in addition is, to my idea, contraindicated for incipient phthisis, and the majority of these sanatoria admit only incipient cases.

Now, if we have to keep the patient occupied, the question arises, in what way? I have mentioned Mr. Grohmann's ideas regarding agriculture, gardening, etc. Nobody will doubt that this is feasible for well-to-do patients. They can buy all the implements and can obtain all the assistance and supervision necessary for such undertaking; but how about the poor? They, too, can be kept busy in many ways which are hygienic. But I go further; not only do I want them to exercise their muscles and strengthen their hearts—that alone is not sufficient—I want them to get some pecuniary return, even if this be but a trifle. In this way they should first help support the sanatorium that harbors them, and, secondly, after their discharge be able to support themselves and their families.

Take, for example, a working-man who makes a very nice living for himself and family. He falls sick, goes to his lodge doctor and is advised to stop working and be out in the open air as much as possible. He has incipient phthisis. The doctor reports him sick, and the brethren from the lodge pay him a visit. They find him enjoying a walk in the park and not looking at all sickly. "Why," they say, "we cannot pay for such a man. He is stronger than we are and ought to work." And back he goes to his cigar factory and works until more serious symptoms arise. Then his brethren believe him to be sick.

Most lodges pay a sick benefit of five dollars or six dollars a week for thirteen weeks the first year; after that the sick member has to rely on his own resources, and the consequence is that after everything of any value has been pawned, this poor man is made a pauper, and is happy when he is admitted to some general hospital to die there, a burden to the community, to himself and his family.

There are several ways to remedy this evil. We must build sanatoria in this vicinity. This surely is to be desired and I truly hope that we shall soon get them. But supposing we have one, or five, or ten sanatoria for consumptives, what does this mean in comparison to the great mass of consumptives we have year in and year out? These sanatoria will hardly be in position to house more than a small proportion of those so afflicted. The great mass will have to go about as before. Now I hold that if the State does not assist us, we ought to help ourselves, and therefore, I propose the following plan:

Take the great many lodges, that give a sick and death benefit. They pay from four dollars to six dollars per week for thirteen weeks, and if the patient dies they pay $500 or even $1000. Would it not be much better for the lodge, as well as for the patient, to give him, say $300 at once and be done with it? With this $300 the man could go to a mild climate, he could commence to work in the open air, and in many cases could survive his disease and make a living.

I think that if a number of these lodges would combine and buy land in the West—where it can be obtained for a very small sum—with the help and supervision of some physicians, these patients would be able to raise material, such, for instance, as the hay that grows in that section called "alfalfa." When a crop of this alfalfa is once started it can be easily reaped four or five times every year. Besides this, there are numerous ways by which these invalids can occupy themselves in a satisfactory manner both hygienically and pecuniarily. There are many reasons which speak in favor of such a plan. (1) The patients would live in a mild climate and enjoy the open air all day long and during a great part of the year also all night; (2) they would have the sun during almost the whole year, and (3) they would be occupied in a manner that is conducive to their health and their material welfare.

The Southwest offers the best chances for such an undertaking; but even in our vicinity, *viz.*, the States of New York, Connecticut, Massachusetts, etc., such institutes could be established and carried on for the benefit of thousands of patients. As each tuberculous patient forms a center of infection, we ought to try to remove them from the city as soon as possible, and if we help them to get on their feet, even in a distant State, we do more charity than if we support all the hospitals in New York.

In conclusion I wish to urge the following points:

(1) All patients with incipient phthisis must be occupied in some rational muscular work. These patients are directed to walk or even climb hills and mountains; they can just as well do some work which will keep them busy. This work should be selected with a view to the financial state of the patient. (*a*) The well-to-do people can do gardening, snow shoveling, light carpentering work, *etc.* (*b*) The poorer ones ought to do, or learn how to do, some work which they can utilize afterward for their own support. Agricultural work, light farming or the others mentioned above would be suitable. (*c*) Every sanatorium should be provided with facilities to teach this as far as possible. (*d*) All this work should go under the supervision of physicians.

(2) Sanatoria for the rich and for the poor should be under one finanical management, although not necessarily in one and the same place, so that the surplus of one institution can help to support the other. This surplus could be obtained partly from the manual labor of the patients themselves.

(3) A society should be formed, if possible, by the people who are mostly affected by it, *viz.*, the lodges, in order to send the patients to a milder climate where they can work constantly in the open air, as, for example, certain parts of Arizona and New Mexico where it is easier for them to make a living in a hygienic way than in the overcrowded eastern States.

It has been stated that an advance in our knowledge of phthisis is shown by the fact that patients can get better in any part of the world, and that they should stay near their homes. Although I am convinced that for many patients a mild mountainous climate is the best, I shall not discuss that question here. I will only ask whether it is not better to send a man away to some western or other climate where he can find a healthy occupation than to let him stay in, or return to New York where he finds no work at all, or has to go back to his sweat-shop and die there.

CLINICAL MEMORANDUM.

A CLINICAL CONTRIBUTION TO THYROID THERAPY.

BY CHARLES E. HIRSH, M.D.,
OF NEW YORK.

ALTHOUGH not quite ten years have elapsed since the introduction of the thyroid gland as a therapeutic agent this treatment has been utilized in a large variety of diseases. As is usually the case with any new remedy whose status has not yet been established, it has been tried in diseases in which *a priori* it could not be expected to give successful results. It would seem rational to conclude that the greatest triumphs of thyroid therapy would be achieved in maladies dependent upon the absence of the thyroid gland or impairment of its function, such as myxedema, cretinism, and some forms of goiter. While this has proved true to a certain extent, clinical experience has demonstrated that thyroid feeding is of value in affections in which no abnormality of the thyroid gland seems to exist, such as various mental affections, certain diseases of the skin, fibroid tumors of the uterus, etc. So little is known, however, concerning the physiology of the gland that its *rationale* of action in these cases cannot be explained, although it appears probable that there is some anomaly of function of the gland in such patients, which is removed by its administration.

The conflicting testimony of authors as to the value of thyroid treatment is evidently due in large measure to the preparation employed. Some clinicians still prefer the administration of the raw thyroid; but for obvious reasons this is impracticable in the majority of instances. The numerous preparations of desiccated thyroid in the market differ greatly as regards their strength in active ingredients. It is now widely accepted that the active substance of the thyroid gland is iodothyrine which was discovered through the brilliant researches of the late Professor Baumann. This investigator found that the quantity of iodothyrine in the thyroid taken from different sheep varied within wide limits. For this reason there can be no uniformity in the various thyroid extracts, since some contain greater and others smaller quantities of active ingredient. This also explains why the effects obtained by different observers have varied so greatly. There is a further disadvantage attending the use of these thyroid products which is connected with their mode of

preparation. They all contain in combination with the active constituent a large amount of albuminous material which is liable to undergo putrefactive processes. According to a number of authorities the unpleasant and injurious effects experienced during the administration of thyroid extracts are attributable to the ptomaines generated through the decomposition of this otherwise inert albuminous material. Iodothyrine is, therefore, to be given the preference over the crude extracts in the market. As shown by the researches of Professor Chittenden and others, it is a body of definite chemical composition which embodies the physiological properties of the thyroid gland. In a paper read before the American Congress of Physicians in 1897 this author stated that in its action on goiter, iodothyrine is more effective than the gland itself, since when the gland is taken it must first undergo digestion to liberate the iodothyrine, and some may be lost by putrefactive changes in the intestine. In a recent article on the treatment of myxedema, Professor Sidney Kuh of Chicago (*Philadelphia Medical Journal*) also states that "with iodothyrine the disagreeable secondary effects were decidedly less marked than when the compressed thyroid were used, a peculiarity which has been observed by others as well as by myself in several instances."

In an article published in the *Medical Times and Register*, March 6, 1897, I reported my preliminary experiences with iodothyrine, and since then my results have been so favorable that I am led to contribute my further observations. The first case which I desire to bring to your notice is one of exophthalmic goiter. I am well aware that the results of thyroid treatment in this disease have been far from satisfactory. In fact, in certain cases, thyroid feeding intensifies the various disorders, and is postively contraindicated. Dr. E. Jeulain, however, last year contributed an essay on an affection designated by him as thyroid chlorosis, which not only represents the symptoms of ordinary chlorosis, but also those of exophthalmic goiter, such as palpitation of the heart, protrusion of the eyes, and an enlargement of the thyroid gland. In connection with these phenomena there were also symptoms of myxedema, such as lassitude and edema. That this peculiar condition was of thyroid origin was well demonstrated by the results of treatment. In the eight cases reported by the author the administration of iodothyrine produced a remarkably rapid and decided improvement. The number of red globules, and the percentage of hemoglobin were greatly increased, the size of the thyroid gland diminished, the tachycardia and the nervous symptoms relieved, and the edema disappeared. As an explanation of the gratifying success obtained from the use of iodothyrine in the case of exophthalmic goiter described below, Jeulain's observations are of much interest.

Case I.—Miss L. J., age nineteen, applied to me for treatment on April 12, 1898. The mother, who accompanied her, stated that her daughter was suffering from heart trouble and nervousness. The patient appeared fairly well nourished, weighing 127 pounds, her height being 5 feet, 4 inches. Her pulse was 110. On examining her more closely I found an enlargement of the thyroid gland and marked exophthalmos, as well as tremor of the flexor and extensor muscles of the wrist. These symptoms, she said, had been present for six months without amelioration, although she had consulted several physicians. To quote the patient's own words: "I got worse and decided to stop doctoring until I stared so and felt so wretched that I was ashamed and afraid to go out into the street." A friend advised her to go to a dispensary; but after going there twice she refused to return. She had used tincture of iodin for the goiter until the skin had peeled off and the surface was abraded. I elicited the following facts from the mother in regard to family history: Parents living; father's age, fifty-nine; mother fifty-four; both in good health; a sister twenty-three years old was also healthy. A brother who died in Honduras six years before also had the same symptoms of which the patient complained—a large tumor on his throat (goiter); the mother stated, however, that he died of asthma. I am inclined to believe his death was due to asphyxia, since dyspnea is a characterized feature of exophthalmic goiter, and as I learned he had several attacks previous. This trouble had been present for four years previous to his death. The patient had not been under treatment for the past two months. Her appetite was poor; her memory had been gradually failing, and she was inclined to be irritable and became exhausted from the slightest cause. I prescribed liquor potassi arsenitis, 3 drops, t.i.d., and also ung. hydrarg. iod. rubr., to be rubbed into the enlarged gland. As no perceptible change occurred under this treatment the arsenic was discontinued, and on April 29 I resorted to the use of iodothyrine, 5 grains, t.i.d., telling her to call in a week. May 6, the patient was feeling greatly improved, but the ointment was discontinued as the rubbing proved too painful. The gland was found to be slightly reduced in size. The dose of iodothyrine was now increased to 7 grains, t.i.d. May 14, the exophthalmos was not as prominent; the goiter was diminished in size, but her heart still annoyed her, the pulse being 106. Digitalis was given in 5 drop doses, t.i.d., and the iodothyrine continued as above. May 19 improvement was progressive; the patient had vomited after taking the last dose of digitalis, but otherwise felt better. The same observation was made on May 27. June 8, the digitalis was discontinued, and the iodothyrine increased to 10 grains, t.i.d. There was still tremor in the flexor muscles; general appearance and appetite better; pulse regular. June 12, increase of dose of iodothyrine to 15 grains, t.i.d., as patient continued to improve. June 15, she suffered from slight nausea and diarrhea. Her weight at this time was 123 pounds, and I told her to stop iodothyrine for a week, as I attributed the nausea and

diarrhea to the increase of dosage. June 23, patient was much better in every way; the iodothyrine was resumed in doses of 5 grains, t.i.d. June 28, the exophthalmos was hardly noticeable, the gland being no longer prominent; the pulse was 100. The treatment was discontinued. July 6, improvement persisted. July 15, the dose of iodothyrine was reduced to 3 grains, as the symptoms were gradually disappearing, and as I desired to determine the minimum dose. July 23, improvement was remarkable, and the treatment was suspended for two weeks, and resumed on August 7, iodothyrine being given in doses of 3 grains, t.i.d. The patient was greatly delighted over her rapid improvement. August 18, the exophthalmos as well as the goiter was no longer perceptible. Her pulse was 92; appetite good, bowels regular. As she complained of some lassitude, however, iodothyrine was suspended for one week, and quinine muriate, t.i.d., given as a tonic. August 27, the patient stated that she felt as well as she did five years ago. In fact, all the symptoms of the exophthalmic goiter had disappeared, the pulse being 88; iodothyrine was continued in same doses. September 19, patient felt well, but had lost 16 pounds since the beginning of the treatment. The remedy was continued, a tonic also being prescribed. October 13, the recovery was found to be complete, and I stopped the iodothyrine. I did not see the patient again until February 7, 1899, when she called at my office. There had been no recurrence of any of the symptoms. April 12, the patient again came under observation, and was also seen July 16 and August 24, and her recovery had remained permanent. In this case iodothyrine was certainly given an impartial trial, and I would ascribe my success to its judicious use.

In my former article I reported several cases of obesity in which a considerable reduction in weight was brought about by the administration of iodothyrine, and since then a number of reports have appeared on this subject. Among these I would particularly mention an article by M. Weiss (*Wien. med. Wochenschrift*, No. 41, 1898) in which he concludes that the favorable effect of iodothyrine in these cases is due to the increased oxidation of the fats, and augmented secretion of urine, without impairment of the nitrogenous metabolism. In one of the cases reported there was a marked cardiac lesion, but notwithstanding this no unfavorable effects were experienced. Dr. H. C. Wood, Jr., in a recent article on the thyroid gland in obesity (*Merck's Archives*, July, 1899) remarks: "It is a well established fact that the thyroid gland is often able, even without any other treatment, to reduce the weight of either corpulent or normal individuals." While he thinks it probable that "there is under the influence of the thyroid gland an increase in the nitrogenous katabolism, not the whole nor even the greater part of the loss of weight can be accounted for in this manner." As will be noted in the following cases, there was an increase of weight after the discontinuance of the treatment, but this was not marked, and cannot be considered as an objection. As Dr. Wood justly remarks, "A moment's thought will show that this is only to be expected, for we are not treating the underlying cause, but merely the symptom of obesity. If, after we have by careful dieting and regular exercise rid a patient of his excess of fat, he returns to his previous habits of overindulgence and physical sloth, of course, he will also return to his previous bodily state. If we wish our treatment of obesity either by the thyroid or diet to be permanent we must insist upon a continuance of abstemious habits, a point on which the originator of the thyroid gland method, Yorke-Davies, lays especial stress." As regards the dosage, Dr. Wood recommends at the beginning from 7 to 15 grains of the fresh gland daily, but says that the dose may be carefully increased if necessary. As will be seen in my cases, I employed doses greatly exceeding these without the least unpleasant after-effects. This is but another proof of the greater safety of iodothyrine over other thyroid preparations.

Case II.—Mrs. A. R., aged forty-three, weight 231 pounds, height 5 feet, 3 inches, consulted me on March 3, 1898. She was the mother of four children; her previous health had been good, but lately her appetite had become poor and the bowels constipated. She could walk only a short distance without becoming exhausted, and was steadily gaining in weight. She had tried various obesity pills, salts, and antifats, but all to no purpose, as they failed to produce the slightest effect. I prescribed iodothyrine, 15 grains, t.i.d., and also extract of cascara sagrada, 15 drops, morning and night. March 9, her weight was 239 pounds; March 16, 228; March 25, 221; April 3, 220. April 11, she felt nauseated, and hence the dose of iodothyrine was reduced to 10 grains. As the bowels were regular the cascara sagrada was discontinued; her weight at that time was 217 pounds. I informed her that to reduce her weight so rapidly without exercise would be dangerous, as she had lost 14 pounds in about five and one-half weeks. In April 18 her weight was 212 pounds; April 26, 210; May 3, 209; May 11, 207 1/2; May 19, 204; May 28, 201. She was ordered to discontinue the iodothyrine for two weeks. June 11 treatment was resumed; her weight up to that time being 202 1/2 pounds. On June 18 it had fallen to 198 pounds, a total loss of 33 pounds in less than 12 weeks of actual treatment. I told her that she had reduced sufficiently, and ordered her to stop all treatment. On August 7 she called again and told me that she had taken plenty of exercise, and had not gained a pound in weight. She was weighed on the same scale, and wore a light wrapper each time. She had experienced no discomfort, except slight nausea on April 11.

Case III.—Miss Mary B., age thirty-five, height 5 feet, 4 1/2 inches, weight 214 pounds, came under treatment March 15, 1899. For the past three years she had been steadily gaining in weight, although in perfect health; the appetite

was fair and the bowels regular. Iodothyrine was administered in 10 grain doses, t.i.d. March 21 there was no change in weight. March 29, weight 211 pounds; April 6, 210; April 15, 207; April 23, 204; April 30, 202; May 9, 196. At this time she had slight diarrhea, for which I prescribed mist. cretæ and salol. May 12, as diarrhea continued iodothyrine was stopped and hydrarg. chlorid. mite., 3 grains, given, followed by mist. cretæ. May 15, the diarrhea had ceased, and iodothyrine was resumed in doses of 3 grains, t.i.d. May 22, weight 189 pounds; May 30, 187; June 6, 187. The dose of iodothyrine was increased to 5 grains. June 14, weight 184 1/2 pounds; June 24, 182. Treatment was now discontinued for two weeks. July 10 the patient desired to resume treatment. July 10 the patient given in 3 grain doses, but as I was very busy I omitted to ascertain her weight on that date. July 17, weight 176 pounds; July 26, 174. I advised her to discontinue the treatment, as I thought she had reduced enough, and her health was perfect. August 16 she called at my request; her weight was then 176 pounds; September 26, 175; October 20, 175. As can be readily seen in this case the treatment has been most successful, as I was able to readily control any increase of weight, and effect a reduction of thirty-nine pounds in four months of actual treatment.

Case IV.—Mr. S. O., age thirty-seven, married, electrician, consulted me May 12, 1899; his weight was 248 pounds, height 5 feet 7 inches. He complained of difficulty in breathing, and can not follow his business with any comfort. He had tried riding a bicycle, and also gymnastics and walking, but without any benefit. His heart was normal, and he experienced discomfort only when ascending and descending the stairs. I prescribed iodothyrine 15 grains, t.i.d. May 18 his weight was 247 pounds; May 25, 240; May 30, 241, a gain of one pound. I increased the dose to 20 grains, t.i.d. June 11 his weight was 236 pounds, but I advised him to stop the treatment for two weeks. July 24, weight 229 pounds; iodothyrine was resumed in doses of 20 grains, t.i.d. August 6, weight 217 pounds; August 23, 211; August 25, patient had a headache and slight diarrhea, and, therefore, the use of iodothyrine was suspended, but was resumed September 5 in doses of 15 grains. His weight at that time was 209 pounds; September 19, 207; September 29, 201; September 30, treatment was discontinued, as the patient had a recurrence of the diarrhea, his weight then being 200 pounds. October 15 his weight was 202 pounds, and the administration of iodothyrine, 15 grains, t.i.d., was resumed. October 26 his weight was 197 1/2 pounds; October 30, 194. The treatment was stopped, although the patient was willing to continue it. He has since reported every week, and has gained two pounds in three weeks, a loss of fifty-four pounds in about five months of actual treatment. The treatment was continued long enough, however, to demonstrate its specific influence without any harmful results.

MEDICAL PROGRESS.

American Folk-Medicine.—In a recent communication R. H. True (*Pharm. Review*, Feb., 1900) cites a few interesting notes on folk-lore medicine of the United States. Some of these empiricisms are as follows: "Swallowing a live head-louse, without the knowledge of the patient, will cure the jaundice." "Biting into a live black snake will insure sound teeth for the one who bites it" is a generally spread superstition. "A sty may be cured by rubbing it with a black cat's tail" comes from Alabama. A unique prescription is current in Rhode Island, thus: "If you have asthma, save all of the nail-parings of your hands and feet for a year. At the end of that time find an ash-tree of the same age as yourself, bore a hole in it, put in the parings and plug up the hole." The following cures for toothache are given: "To bite into a living black-snake will cure the toothache," and "picking the teeth with a splinter from a tree struck by lightning will prevent toothache." The old German folk-lore belief that "thoroughwort" will act as an emetic or as a cathartic, according to whether the plant is brewed with the "blows up or blows down," is closely matched by the Ohio tradition that tea made from elder bark removed by scraping upward will act as an emetic, whereas if the bark be scraped downward the tea will have cathartic properties.

Day-terrors in Children.—The occurrence of day-terrors in children has received but little attention. Much has been written of night-terrors, as they are common, but English writers, at least, have given but little attention to the much less common attacks which occur during the waking moments. G. F. Still (*Lancet*, Feb. 3, 1900) reports five cases of this interesting condition, all in children under the age of six years. In most of the cases, the child without warning begins to scream, has a terrified look and runs to his mother or attendant, hiding his face in the folds of her garment, and gives every evidence of suffering from great fear. Hallucinations and delusions seem to be absent. In literature cases are reported which have occurred in older children. In some of these distinct evidences of visual and auditory hallucinations were obtainable. The relation to night-terrors is probably very close. In four of the cases reported night-terrors were, or had been, present, and it would seem that the day attacks may be associated with them or replace them; but the two conditions are probably very different in etiology, although the etiology of night-terrors is far from being known. A nervous, excitable temperament is nearly always a factor in the etiology. Rheumatism, either in the child or in the parents, may play some rôle. In most of these children minor functional neuroses are evident. Habit spasms, nocturnal enuresis, recurring headaches, nervous diarrhea are frequent with them. In a large number valvular disease is present. Some observers have claimed

that night-terrors, and more particularly, day-terrors, are epileptic in their nature, and that the condition is to be considered as a form of *petit-mal.* This is not the view held by the author. He believes that, inasmuch as these patients do not show any tendency to attacks of major epilepsy and, furthermore, are so readily relieved of their symptoms by appropriate treatment, that the relation to epilepsy must be but very slight, if any relationship at all exists. In some cases there seems but a very narrow line existing between day-terrors and some forms of insanity. The author's summary of impressions, for thus far in the study of this affection it is only possible to have impressions, is that it is a paroxysmal psychoneurosis allied to, but not identical with, epilepsy on the one hand and hysteria and insanity on the other. The prognosis is good. The most important part of treatment is the removal of any exciting cause. Since a chronic intestinal catarrh is apt to be present, it should be relieved. Potatoes, pastry and the sugars are to be excluded from the diet. Thread-worms or other intestinal parasite must be removed. Potassium citrate and the bromides are useful and a regular mode of life with healthful distractions and non-exciting sports will usually aid materially in the treatment.

Submucous Fibroid: Uterine Section.—J. Braithwaite (*Brit. Med. Jour.,* Feb. 3, 1900) successfully removed a large submucous fibroid at the fundus by doing practically a Cesarian section. After opening the abdomen an elastic ligature was passed about the cervix, and section of the uterine wall made down to the fibroid, which was easily removed. The cavity of the uterus was opened so a drain was passed through the cervix after removal of the ligature. The wound was closed as in Cesarian section, and primary union resulted.

Renal Papillectomy.—E. H. Fenwick (*Brit. Med. Jour.,* Feb. 3, 1900) has been studying painless unilateral renal hematuria in young adults for years to get at its etiology. Kidneys which have been bleeding freely and persistently show no lesion on the post-mortem table nor under the microscope. In a number of cases he has incised the kidney through the cortex, inserted his finger and discovered nothing abnormal, yet the bleedings ceased. He believes the failure to discover the cause of hemorrhage must be due to faulty technic. In his last two cases, he has opened the renal pelvis, inserted an electric light, and in each case has been rewarded by finding one papilla markedly congested, somewhat swollen, and bleeding freely. This papilla was removed and the wound closed. Hematuria never recurred. Examination of the specimen, which resembled a vellous growth, showed it to consist of markedly varicose, congested veins, with extravasation of blood and an increase in cellular stroma. This condition cannot be made out by finger exploration.

Improved Suture for Fractured Patella.—R. G. Pattison (*Brit. Med. Jour.,* Feb. 3, 1900) thinks the causes of bad results in suturing fractured patellæ are as follows: (1) The adoption of a subcutaneous method in which no effort is made to relieve the tension in the joint due to extravasation of blood and serum and in which, therefore, the bony surfaces cannot be accurately apposed. (2) The use of unsuitable sutures and a faulty technic, leading to joint infection, or the cutting out of the sutures, and consequent loss of apposition. His method is to make a U-shaped incision, crossing the patella ligament well below the lower fragment. The periosteum is reflected from the front of each fragment and the joint cavity washed free of clots by sterile water. A hole is drilled obliquely, so as not to pass through the posterior surface, through each fragment in the median line. A specially designed semi-cylindrical, soft silver wire is then passed through, so that the broad, flattened surface, which is least apt to "cut through the bone," sustains the tension later. The joint is now again flushed out, the fractured surface accurately apposed, the silver wire tightened, fastened, and flattened out. The periosteum is now sutured over the silver wire and line of fracture and the skin closed. He begins passive motion about the fourteenth day and soon has the patient up on crutches. This is the ideal treatment of fractured patellæ in the young and healthy. Special emphasis is put upon the following points: (1) Delaying operation a few days till the more acute joint symptoms subside; (2) thorough cleansing of the joint cavity and fracture surfaces; (3) the use of a single sterilized suture so shaped as not to cut the bone, and not to form a large irritating knot when it is fastened; (4) the elevation of the periosteum and its subsequent suture over the embedded wire which help to prevent infection and irritation; (5) the early commencement of passive motion, thus shortening the period of disability.

How Malaria is Transmitted.—The belief that mosquitoes bear a causal relation to malaria was expressed by Roman writers two thousand years ago, but it has only been in recent years that any attempt has been made to prove the truth of this suggestion. In the *Medical Record* (Feb. 17, 1900) I. P. Lyons has reviewed the literature upon this subject and gives a *résumé* of the investigations made, especially those by Grassi, Bignami, Bastianelli and Dionisi. The ordinary mosquito (Culex) was found to be harmless, but several species of the Anopheles have been successfully inoculated with the tertian and estivo-autumnal parasites, the development of these parasites in the mosquito carefully watched, and the final return of the spores to a human being with the subsequent development of the disease has been successfully accomplished. Practically every step has been followed with the tertian and estivo-autumnal parasites, and the quartan parasite has been followed up to the coccidial stage in mosquitoes, although it has not yet been made to

return to its human host by the bite of mosquitoes. It is thoroughly believed, although not entirely proven, that malarial infection is produced only by the bite of mosquitoes. The harmless Culex lays its eggs on the surface of artificial collections of water while the Anopheles seems to prefer natural bodies of water on the outskirts of towns and in rural districts. The extermination methods must deal with the larvæ and these can be successfully combated by drainage of the pools, by the introduction of fish, or by scattering petroleum or other chemicals over the surface. It is further urged that any case of malaria may be a menace to the public health provided the Anopheles be also found in the same locality and, hence, it follows that every case should be carefully isolated by mosquito netting or otherwise.

Tannopin.—C. Tittel (*Therap. Monatshft.*, Feb., 1900) has obtained some excellent results in intestinal disease of children with tannopin, and considers it decidedly superior to the other recent astringents. The drug, which is a condensation product of tannin and urotropin, forms a dark-brown insoluble powder which in the small intestine splits into its two components. It does this very slowly so that its action is continued in the large intestines, as can be seen by the increased consistency of the stools and the disappearance of the mucus. Since it contains urotropin, it is markedly antiseptic. In mild cases recovery results in from two to three days. It may be added to cod-liver oil if this causes loose movements.

Therapeutics of Splenic Extract.—The use of extracts of animal organs in the treatment of disease will, no doubt, furnish a wide field for valuable discoveries in the future, and give to the medical profession specific remedies for many diseases which are now treated symptomatically. C. R. Carpenter (*Med. Record*, Feb. 17, 1900) has been experimenting with a few cases of typhoid fever by using the extract from the spleen, and explains very satisfactorily the theory upon which he bases his faith in its value. Most acute infections and especially pyogenic diseases cause a leucocytosis which varies largely with the severity of the disease and with the resisting power of the patient's system. In other words, the leucocytes act as defenders against the poisons of disease, but may have assistance from undetermined antitoxic principles in the blood. In typhoid fever there is usually a diminution in the number of leucocytes except early in the disease and when complications occur. This condition is explained by the supposition that the spleen is the chief generator of leucocytes and being one of the organs early involved in typhoid fever, its function is interfered with or destroyed. It is further maintained that the chief benefit derived from the use of the cold-bath treatment is due to the increase of leucocytes which it causes. The mere reduction of temperature cannot explain all the beneficial results which are obtained. Experimentation has shown that the extract of the spleen produces a leucocytosis, and, since it is that organ in particular which is involved in typhoid fever, the deficiency is supposed to be supplied by the administration of its extract, just as the extract of thyroid performs the function of a diseased thyroid gland. The cases upon which the extract of the spleen have been tried were few in number, but most favorable results were obtained and it is believed to be a specific in the disease, aborting its course just as the antitoxin of diphtheria does. It is given in doses of five grains every three hours for the first twenty-four hours, at the end of which time the temperature usually falls one or two degrees. The extract is then given in doses of five grains three times a day. When an anemia is present a hematinic is essential.

Drugs in Obesity.—While the dietetic and hygienic plans give the best results in excessive deposits of fat, many drugs have been recommended. H. Kisch (*Therap. Monatshft.*, Feb. 1900) finds that, while an occasional purge is beneficial in many cases, especially if with hyperemia of the abdominal organs, the constant use of drastics will lead to diminished absorption of food from the bowels and hence actual malnutrition. Alkalies likewise must not be used for any length of time. Vinegar is believed by many to cause increased fat dissolution, but what really results with this, as well as with iodine and the iodides, is a cachexia from chronic poisoning. The latter are only indicated in advanced cases where a rapid reduction is desired, but to the external use of iodine there can never be any objection. Pilocarpine, which like other diaphoretics would increase the heat-radiation from the skin and thus stimulate fat-metabolism, is to be used with great caution where a fatty heart is present; steam-baths act similarly, but also require a healthy heart and arteries. Recently the virtues of thyroid extract have been voiced by many, but it is inconstant in action and fatigue, diminished muscular power, glycosuria and other symptoms have appeared, since it possesses no selective action on fat but attacks proteids as well. If given, the patient is to be carefully watched and the dose must be small.

Treatment of Obesity.—In a recent number of *La Presse Médical* Professor Herman Cohn of Breslau describes Dr. Schweninger's obesity-cure as administered in an establishment in Baden-Baden. The method was decidedly strange, but the results were marvelous, some patients having lost 20 pounds in five weeks, 50 pounds after eight weeks, and, in one case 95 pounds in nine months. All the concomitant symptoms of obesity also improved under this treatment, which consisted of (1) massage of the abdomen, (2) hot baths, and (3) diet. Massage was performed three times a day, before eating, and each treatment lasted fifteen minutes. The patient lies on his back with legs and thighs flexed, and the physician begins by tapping, at first lightly, then with greater force, upon the epigastric region, until he

sinks his two fists as deeply as possible into the abdomen of the patient. During this procedure the patient is supposed to breathe deeply and regularly in order to exercise his diaphragm. In fact, at first the patient can only take five deep respirations, because of the pain, but later he can take twenty deep respirations. The operator now grasps "large pieces" of the abdominal walls in his hands and squeezes them as hard as possible in order to crush the subcutaneous fat lobules. The patient's abdomen is soon covered with bruises. The pain during this "gentle" procedure is such that groans and tears are elicited. And last, but not least, the physician now gets upon the patient and sinks his knees as deeply as possible into his abdomen—especially in the epigastrium —while the poor patient tries to take at first five and later a greater number of deep respirations. That any one could survive this treatment once seems wonderful, but to go through it three times a day! The patients after a while really got used to it, but being a little tired after this massage they usually remained resting on the couch for some time. The hot baths were given in instalments. The first day the arms had a bath, the second day the legs, the third day the hips, the fourth day the arms again, and so on in the same order during all the treatment. Entire baths are never given. The temperature of the baths is at first 99.5° F., gradually increased up to 122° F. The baths last for twenty minutes each. The fatigue following these baths causes the patient to sleep for some time. The diet is peculiar. The dishes and plates are of doll's sizes. The glasses barely hold eleven drams of liquid, and even the knives, forks, and spoons are small. The meals are served every three hours, the patients eating in their rooms, and it does not take long to eat a meal. Everything is served in minute portions. The usual diet limitations are observed. The patient may get for the first breakfast a small slice of cheese, or ten prunes, or one egg, or a plate of turnips, or carrots, or a plate of clotted milk, or a slice of ham. For the second breakfast there is a little meat, or an egg, or a vegetable. At dinner a small slice of roast meat, or a slice of chicken or calf's-liver. The other meals are on the same plan. The patients do not drink with the meals, but half an hour after they are allowed to drink one of the little glasses of Sprudel or Gerolstein water. The total quantity of water allowed each patient a day is about one-half a liter. If they get thirsty a pear or a prune must satisfy them.

Treatment of Phthisis Pulmonis.—A detailed and extended review of the treatment of pulmonary tuberculosis is made by G. A. Evans (*N. Y. Med. Jour.*, Feb. 17, 1900) who has had a wide and valuable experience. In the incipient cases he advises the hygienic and climatic methods as the most serviceable, and claims that the western slope of the Appalachian system from Maine to Alabama is the region which affords the best results. The proper treatment for cases after necrosis of tuberculous tissue has begun, and after evidences of local sepsis and septicemia have appeared, is drainage, to stop the absorption of septic agents and above all to limit or prevent self-infection. The only method of drainage is by expectoration, but the use of internal remedies merely acts by increasing the flow of mucus and as the seat of disease is frequently on the distal side of the mucous glands in the smaller bronchioles and alveoli this method is only partially efficacious. Clinical experience has shown that it is impossible to inspire compressed air where an albuminoid fluid is present in the air passages without causing its expectoration, and that the bronchial tubes and pulmonary alveoli which are at all permeable by atmospheric air are much more so by compressed air. The combination of an antiseptic with the compressed air has given excellent results since the local application of a germicide is aided by the marked increased drainage by expectoration. Twenty-five to thirty-five per cent. solutions of phenol in equal parts of glycerine and water are used in the form of a fine spray for thirty minutes every day under a pressure of about one twenty-fifth of an atmosphere. When cases are not too far advanced complete recovery is claimed.

Treatment of Lobar Pneumonia.—H. Eichhorst (*Therap. Monatshft.*, Feb., 1900) thinks that venesection is done too rarely at the present day in pneumonia and praises its life-saving effect in complicating pulmonary edema. Digitalis should only be employed when the heart demands it and the practice, to begin every treatment with this drug, is to be severely criticised. In many young and strong patients, all medicinal treatment is unnecessary. The rules for alcohol are much the same as for digitalis; it is especially useful in the old and in drinkers and the latter drug often works better if preceded by alcohol. For quick stimulation of the heart caffeine hypodermically is often preferable to digitalis, while injections of camphor are to be resorted to in the more serious cardiac disturbances. Narcotics are to be avoided since cough and expectoration may be suppressed and the bronchi thus become filled; in cases with delirium and restlessness morphine may, however, be demanded. Antipyretic treatment by means of phenacetine and baths is indicated where high temperatures are badly borne; in other cases it is unnecessary. All so-called specifics have failed to prove their reputed value and blood serumtherapy has in most cases disappointed.

Oliver's Hemocytometer.—In the *Boston Medical and Surgical Journal* (Feb. 15, 1900) David D. Scannell describes the principle upon which Oliver's hemocytometer is based, the apparatus required in the process of the examination and the technic of such observation, and also gives the results in 27 cases in comparison with those obtained by the Thoma-Zeiss counter in the same cases. The time required for the whole process by Oliver's hemocytometer is only about ten or

fifteen minutes and is a gain over the half-hour usually expended in the preparation and count when the Thoma-Zeiss apparatus is used. The apparatus required for such observation consists of (1) a flattened tube, 15 mm. in the long diameter and 5 mm. in the short diameter, graduated so that in a scale of 12 centimeters, 100 per cent. being equal to 5,000,000 corpuscles per cubic millimeter, the divisions represent two per cent. each; (2) a capillary pipette with a capacity of 10 cubic millimeters and with a lumen large enough to clean easily; (3) a mixing pipette, or ordinary medicine dropper, provided with a rubber nozzle which fits over the small end of the capillary pipette; (4) a small-sized wax candle; (5) a fixing solution, preferably Hayem's. This solution consists of hydrarg. chlorid. corrosiv., 0.5 gm.; sod. chlor., 1.0 gm.; sod. sulph., 5.0 gm.; aq. dest., 200 c.c. and (*a*) is cleanly; (*b*) does not affect the corpuscles as much as other solutions; (*c*) there is no varitaion in the reading even after twelve hours, so that all of the examination need not be made at once. The mixing pipette being filled with Hayem's solution, the capillary pipette is filled with blood, the rubber nozzle of the mixing pipette quickly fitted over the blunt end of the capillary pipette and the 10 cubic millimeters of blood thoroughly washed into the flattened tube by the compression of the rubber bulb of the dropper. The filling of the capillary pipette with blood and the washing of the blood into the flattened tube should be done quickly lest the blood coagulate in the capillary tube. After the blood is washed out of the capillary tube, detach it from the medicine dropper and make further additions of the fixing fluid from the latter. The contents of the flattened tube are gently but thoroughly mixed after each addition of the fixing solution. The observation is made in a dark room with the candle ten feet away from the observer and the tube held close to the eye. As the fixing fluid is gradually added, drop by drop, the observer must watch carefully for the first appearance of the transverse line of light, so as not to add any solution after the transverse line becomes complete. In 27 cases examined by both the Thoma-Zeiss and Oliver's hemocytometric methods there was a marked similarity in the results, the average difference being only 35,000, or less then one per cent. In successive hemocytometric observations in the same case within a short interval the two readings were identical.

Bacteria and Diabetes Treatment.—Some time ago the bacterial origin of diabetes mellitus was suggested and the use of antiseptics such as bichloride of mercury and auri et sodii chloridum advocated. J. P. Sheridan (*N. Y. Med. Jour.*, Feb. 17, 1900) claims that these remedies do not diminish the glycosuria, but tend to reduce the oxidizing power of the red blood-cells, thereby producing rapid emaciation. Working on the theory of bacterial origin, however, he has used a combination of bromide of gold with bromide of arsenic, called arsenauro, with most favorable results in four cases which he reports. The drug should be pushed to the physiological limit which is shown by the development of symptoms of arsenical poisoning.

The Lymphatic Diathesis.—Lemoine (*Le Nord Médical*, Feb. 1, 1900) says that changes in the blood, the bone-marrow, the spleen, the lymphatic ganglia, and the lymphoid tissues characterize this condition, any or all of these being diseased. The general symptoms are anemia, debility, dyspnea, and in the late stages, emaciation with hemorrhage and edema. For treatment, hygienic measures are indicated, such as fresh air, short and frequent walks, nourishing food, especially milk, eggs, fat and starchy materials; laxatives to promote intestinal secretions, with bitters and tonics, inhalations of oxygen, and massage, frictions, and cold douches in the region of the spleen. Among the drugs in common use ferric chloride, protoxalate of iron, quinine, and cod-liver oil are the best as tonics. Iodides may be given in scrofulous conditions and will diminish the adenitis, but they tend to increase the wasting, the epistaxis, and the visceral complications. Phosphorus and mercury are useless or harmful. Ergotine or hydrastis or perchloride of iron may be used for the hemorrhagic tendency, and quinine if malaria coexists. Bone-marrow promises well, but has been little tried. Universal experience indicates that the best general remedy is arsenic. Of this, Fowler's solution may be given in large doses internally, combined with laudanum to prevent disagreeable effects; or, if the diluted Fowler's solution is injected interstitially into the affected gland or into the spleen, it not only affects the whole system, but causes a rapid and marked atrophy of the tissues at the seat of the injection. Mineral waters and baths may aid in the general treatment, and in cases of isolated lymphadenoma the disease may be checked by early surgical removal. Surgical treatment, however, has met with but little success.

Origin of Toxins in Burns.—To determine the influence of the skin in producing the poisons which lead to a fatal issue in burns, E. Scholz (*Münch. med. Woch.*, Jan. 30, 1900) conducted two sets of experiments, in the first of which large scalds of the peritoneum were compared in effects with similar traumatisms to the skin. The animals with the peritoneal wounds showed more severe symptoms, hence it is fair to assume that the skin is not the only source of the toxins. The second series contrasted the results following burns on hyperemic and anemic skin; in the former case the rabbits died with convulsions, while in the latter no ill results were noted. It is thus concluded that the blood itself, rather than the tissues, is the seat of the chemical change.

Antitoxin for Diphtheria Immunizing.—The New York Board of Health reports show that there were about 700 more cases of diphtheria during 1899 than during 1898 and that the death-rate was 13.1 against 12.2 per cent. in 1898. J.

S. Billings (*N. Y. Med. Jour.*, Feb. 17, 1900) draws attention to the fact that although the antitoxin treatment of diphtheria acts as a specific and effective curative remedy, it cannot bring about any marked decrease in the number of cases since the disease spreads rapidly and easily from person to person through many channels, and perfect isolation is almost impossible, especially among the poorer classes. He urges, however, that the prophylactic use of the antitoxin will furnish an effective means of lessening the number of cases and points out that there were over 600 less individuals immunized during 1899 than during 1898. In over a thousand cases immunized only six contracted the disease, which was in every instance mild in form. It has been found that 150 units is not always successful and that it is much better to use 300 units in children and 500 units in adults to immunize against the disease. Furthermore the reactionary symptoms are not so great when the larger dose is used.

Fleas and the Plague.—The daily as well as the medical press, taking its cue from Simond's article on the transmission of the plague in the *Annales de l'Institut Pasteur*, 1898, have regarded the flea as a probable agent in the spread of the plague. The fleas which live on infected rats and mice are supposed to bite human beings and thus infect them. Bruno Galli-Valerio (*Centralblatt f. Bakteriologie*, Jan. 6, 1900) disputes Simond's conclusions on the following grounds. The flea that bites man (pulex irritans) has an ovoid body, is reddish-brown in color and has no characteristic comb-like structure on the head and prothorax. The flea of rats (typhlopsylla musculi) has a thin body, is yellow and has spines along the head and comb-like structures on the thorax. Other species of flea are found on the mouse. The important feature is that none of these fleas bite man and Galli-Valerio, notwithstanding the fact that he placed fleas on his body—under watch-crystals—was unable to make them bite him. He therefore concludes that this means of transmission is not probable. He does not, however, give us any data as to what a hungry rat-flea may do under unknown circumstances.

Curability of Epilepsy.—That the usual definition of epilepsy, as a "disease characterized by tonic and clonic spasms and followed by a loss of consciousness," does not describe the conditions with scientific accuracy in a large percentage of cases is brought out by W. P. Spratling, Medical Superintendent of Craig Colony (*Medicine*, Feb., 1900) who from a wide experience shows that many patients have tonic convulsions only others, clonic convulsions; while a large number have very incomplete loss of consciousness. Epilepsy in its initial stages he divides into two groups, the *false*, which includes such cases as may be traced to a true physical cause, recent in origin, and the *true*, which includes cases which have congenital or acquired organic defect or deficiency of the brain. The former group includes many cases which are readily cured and form the basis of the claims of eye specialists, gynecologists and others, who cure some cases by trifling operations. The second group demand much attention and a serious prognosis is always present. Spratling is emphatic in his disapproval of the use of bromides for all classes, especially in children. For the pronounced epileptic Colony treatment is the best form. This treatment, as outlined, is as follows: (1) The colonizing of the patient means that he is placed under such restrictions that at all times entire control of his acts is secured. (2) He is treated as an individual at first, along broad hygienic lines, for many come in poor general health, and the first demand is that they be built up, reconstructed physically. (3) To do this a diversity of means is employed. Medicines, systematic occupation, gymnastic exercises, baths, special feeding, and the use of such moral agencies as may be essential. (4) All the while he is being studied for aura; for the presence in the blood, urine, or other secretions of noxious substances that may cause or help to cause the disease. (5) He must eat only such food and only in the manner prescribed for him. This is regarded as most essential. (6) He must not overeat, for by tradition founded on fact he is apt to gormandize. (7) He is not permitted to use alcoholic stimulants in any form or to any extent. Tea or coffee, if properly made, may be taken in moderation. Tobacco may be used in moderation. (8) At the Colony every epileptic received is made to undergo a complete change of life. If he was of sedentary habits he is put out in the fields, under the sun and in the air—not abruptly, but gradually. His entire life, as far as can be, is thrown into new channels. If, when received, he is feeble, as many of them are who have suffered from long neglect, he is put into the hospital, fed on light nutritious foods, and every effort made to build him up. (9) If it is seen at any time that he fails easily under any mental strain, such as study or close reading, he is made to abandon such pursuits and use his body only. (10) If his body is big and strong and he is weak intellectually, then the opposite course is pursued, the object always being the coequal development of the mind and body—no vitiation of one at the expense of the other. (11) If he has any natural bent or inclination in the way of study or work, it is recognized and encouraged, for mental occupation in the treatment of epileptics is an important factor. Due heed to the foregoing over a sufficient time has cured from six to eight per cent. of all cases that came to the Craig Colony.

For Menstrual Pains.—*Gazette hebdomaire de Paris* gives the following formula:

℞ Codein.....gr. ¾
Chloral.....gr. xv
Ammonium bromide.....gr. xv
Aquæ camphoræ.....3i.
M. To take in two doses.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 Fifth Avenue, New York.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, FEBRUARY 24, 1900.

DIET IN CONSUMPTION.

Patients who have been successfully treated in German and Swiss sanatoria insist especially upon the quantities of food that they found themselves able to consume under the direction of their physicians. At Nordrach, for instance, the rule is for the patient to eat twice as much as he has previously been accustomed to eat, and patients very soon fail to find it the task they anticipated.

Abundant food is a very serious consideration; for the weight of the patient is an important element in his constitutional resistive vitality. Some years ago the New York Mutual Life Insurance Company showed from mortuary statistics that "of persons with untainted family histories twice as many died among those who were under weight with respect to their height as those above the average weight; that family history influenced the consumption death-rate far less than the personal condition (referring especially to the normal weight), and that it is, therefore, a far less valuable indication of an underlying phthisical predisposition."

All experience coincides in proclaiming the vital importance of a gain in weight for patients suffering from consumption. Practically all the lauded specifics for the disease have been such as acted as tonics and increased the appetite. The influence of suggestion in all cases of tuberculosis seems undoubtedly due to this tonic effect of renewed hope upon the patient. The great specific concealed behind all the others that have been used, and making them all for a time seem of value, is the increased consumption and assimilation of food that they have induced. It is this that must constitute the groundwork of any successful method of treating consumption, and just as soon as the general nutrition fails to improve, any remedy or method of treatment will inevitably fail.

THE PATHOLOGY OF INSANITY.

The brain has been justly regarded as a most mysterious, obscure and Sphynx-like region in its manifestation of disease. Partly because the lesions accompanying mental diseases are so slight, and partly owing to the complexity of the nervous system of man our knowledge of the pathology of insanity is in a very crude state in comparison with that of other diseases. Insane asylums are full of instructive material, but hospital physicians, too busily occupied with the requirements of routine administration, have unfortunately let slip their opportunities to enlarge this sphere of knowledge.

New York led the way in revolutionizing this condition, by organizing a Pathological Institute for the insane asylums of the State, where pathologic material could be worked up by experts and correlated with the clinical experiences of the physician attending the cases. Whether this same need of such an institute had been more slowly finding its way to concrete expression in London, or whether the London County Asylums caught the idea from us, and immediately put it into action, we cannot say.

The first volume of the "Archives of Neurology" from the Pathological Laboratory of the London County Asylums has just appeared, and it is with a feeling of pleasure that we realize that the men in London have accomplished a much desired work. They have "ushered in an era of accelerated progress in the scientific unraveling of the maze of mental pathology."

General paresis has received the greatest amount of attention during the past year and the potent influence of syphilis has been clearly brought out by the investigations. Some twenty-four articles on allied subjects have been worked

out by Dr. Mott and his staff of assistants and physicians to whom the privileges of the laboratory have been extended. No narrow spirit of investigation has prevailed. Statistical, historical, racial and geographical considerations have been studied in connection with the clinical and pathological questions. The "Archives of Neurology" contains the work of the technical micropscopist, the chemist, the biologist and the practising physician, and counts research a progressive, comprehensive study, not a mere "microscoping" and "test-tubing."

If the yearly output of work equals that of the past twelve months, alienists will look to the Archives for brilliant results. The only regret we can express in connection with its appearance is that the name chosen is almost identical with that of the publication of the New York State Pathological Institute.

ANTIVIVISECTION ONCE MORE.

Prominent antivisectionists gave due warning years ago that they hoped to succeed by keeping unremittingly at it in securing the utter abolition of animal experimentation. True to their promise the bill for the regulation of experiments upon animals in the District of Columbia comes up at every session of Congress. This law, it is confessed by the antivivisectionists themselves, is meant to be only the entering wedge for legislation along similar lines throughout the country. The prestige of a legislative victory at the national capital would carry great moral weight with the State legislatures. Moreover, the Government laboratories, most of them, are situated in the District of Columbia and the blow is especially aimed at them, since, so long as animal experimentation is carried on directly under authority from the Government, the opponents of experiments upon animals cannot hope to prevent this method of investigation at other places.

The gauntlet has been definitely thrown down. The battle for the right of experimentation on animals is on. Each succeeding session of Congress sees the struggle renewed. If the medical profession of the country would not see invaluable opportunities for the investigation of disease in this country ruthlessly snatched away because of irrational fanaticism, it must not tire of this ever-recurring contest.

We venture to say that in recent years the cause of antivivisection has gained more adherents than has the principle of animal experimentation. This is mainly due to the fact that a most persistent and untiring propaganda of the doctrines of the antivivisectionists has been made. Fanaticism has a special attraction for our generation. It is only necessary to recall in this connection how many supposedly intelligent persons are carried away by the shallow absurdities of Christian Science. There are any number of people constantly on the lookout for some new fad. When their latest hobby happens to be antivivisection they become most earnest advocates and zealous propagandists. As an offset to all this every doctor should make it his business to spread the light of a right understanding of the position of the profession in this matter. Only in this way can we be assured that offensive legislation will not eventually be enacted. Apathy because of confidence in past defeats of the bill may at any time lead to enactments that would not only seriously cripple the great work of the Government laboratories, but start a wave of legislative enactments that would be felt disastrously in every experimental laboratory of the country.

ECHOES AND NEWS.

NEW YORK.

Harlem Hospital Trouble.—The House Physician, Dr. Campbell, has been suspended for three months and the visiting physician, Dr. Haubold, for one week, owing to a general family quarrel that had arisen among the physicians, the superintendent and some subordinates.

Some Seceders.—Owing to certain developments in the arrangements for the Tuberculosis Congress announced to be held under the auspices of the Medico-Legal Society, Drs. J. Blake White, L. A. Knopf, Egbert Le Febre and Charles E. Quimby have withdrawn their names and influence from any connection with the Congress.

Dr. McCosh.—We are gratified to be able to announce that Dr. Andrew J. McCosh, as we go to press, is rapidly recovering from the septic infection from which he has been suffering since Thursday, February 15th. On that day he became inoculated with some unusually virulent sepsis while performing laparotomy upon a child who was afflicted with a purulent general peritonitis.

State Hospital Buildings.—Under the Charter of the City of New York the authorities of the city have claimed the right to inspect the buildings and direct the manner of their construction, and also to inspect the boilers of the Long Island and Manhattan State Hospitals. Attorney-General Davies decided, on February 16th, at Albany, that the city has no such jurisdiction.

The Influenza.—Superintendent O'Rourke of

the Department of Charities reports that there is a constantly growing number each day of patients suffering from influenza being admitted into the public hospitals. The wards for pulmonary diseases in most of the hospitals are full and cots in other wards are being used. The increased number of cases of bronchial and pulmonary affections in private practice is also marked.

The State University.—The *School Bulletin* announces the failure of Governor Roosevelt's Unification Commission in the reorganization of the State University. It says that there seems to be general agreement that the bill stands no chance whatever of becoming a law; it has already been thoroughly discredited by the public press, and in fact was introduced only with apologies in each House of the Legislature.

Contagious Diseases.—For the week ending February 17, 1900: Measles, 891 cases and 21 deaths; diphtheria, 310 cases and 43 deaths; laryngeal diphtheria (croup), 29 cases and 11 deaths; scarlet fever, 212 cases and 21 deaths; smallpox, 1 case; chicken-pox, 42 cases; tuberculosis, 183 cases and 166 deaths; typhoid fever, 19 cases and 5 deaths, cerebrospinal meningitis, 10 deaths. Total, 1687 cases and 277 deaths.

Charities and Corrections Departments.—A bill has been introduced into the State Legislature empowering the Commissioner of Correction to remove from his department to that of Charities any person committed as a vagrant upon certification that the person is aged, feeble and infirm, and mentally and physically unfit to perform manual labor. Commissioner Keller is opposed to this measure and is using his influence against its passage.

Yellow Fever from Santos.—A fireman aboard the German steamship "Taormina" of the Sloman Line, which arrived February 19th, from Santos with a cargo of 34,100 bags of coffee, died of yellow fever on February 12th, when the ship was seventeen days out. He was buried at sea. A fireman and messmate of his fell ill with the fever just after the latter's death. He was removed to Swinburne Island Hospital. The "Taormina" is detained for disinfection. She will proceed to the upper bay and discharge her cargo into lighters.

J. Hood Wright Memorial Hospital.—According to the annual report, 1357 cases were treated during 1899 in the emergency ward of this institution; 1164 patients were attended by its ambulance surgeons and not taken to the hospital; in all 8809 persons received care. In December the hospital ended its thirty-sixth year as a dispensary, established by Dr. Rodenstein, and the fourteenth year of its added work as a hospital, free of debt and with property worth $100,000. The receipts for 1899 were $21,202.29; the expenses amounted to $23,164.92.

Arrest of an Epileptic.—Hugh Higgins, Jr., an epileptic, who has been for years under treatment by Dr. William B. Noyes at the De Milt Dispensary, fell in a fit while on his way to visit friends in Brooklyn. A policeman arrested him on a charge of vagrancy and intoxication, and he was committed to jail for twenty-nine days. His father, on learning of this commitment, went to court and upon his statement of the circumstances Higgins was at once released. The patrolman should at least know when it is necessary to have a physician's opinion.

City's Population and Death-Rate.—The Board of Health has prepared an estimate of the population of this city on January 1, 1900, and an estimate of the death-rate for the first week of February. The population numbers 3,654,594 and the death-rate is 18.09 per 1000. Brooklyn Borough has the lowest death-rate, 16.35 per 1000. Manhattan has a death-rate of 19.65 per 1000 of estimated population. During the week ending February 3rd there were 1631 cases of contagious diseases, of which 118 died. One of these deaths was from beriberi.

Homeopathic Medical Society.—The Homeopathic Medical Society of New York State, at a meeting at Albany, on February 14th, elected the following officers: President, W. W. Butler of Brooklyn; first vice-president; E. W. Bryan of Corning; second vice-president, L. A. Martin of Binghamton; third vice-president, Emily Swett of Medina; secretary, Dewitt G. Wilcox of Buffalo; treasurer, Charles Deady; necrologist, W. S. Garnesey; nominees State Board of Medical Examiners, J. W. Garrison of New York, E. E. Hasbrouck of Brooklyn, Asa S. Couch, J. W. Candel and J. M. Lee.

Disposal of Garbage.—Representations of the Barren Island Reduction Plant were heard by the City's Committee recently in opposition to the bill before the Legislature for the removal of the plant. They maintained that the plant had been constructed at a cost of $600,000; that it consumed the garbage of the Greater City at practically no expense, the products paying the expense of the collection of the garbage and the operation of the plant. During the past two years the company has expended about $60,000 to remedy the features that were complained of as nuisances; there is now no offensive odor about the plant, and the only complaint is from the smoke and odor issuing from the chimneys. They thought these conditions could be corrected and they are willing to expend what money is necessary to accomplish it. The expense of an incineration plant, as proposed in Senator Wagner's bill now before the Legislature would be something enormous. The original expense would be about $13,000,000, and the expense of running the plant would probably cost the city a million and a half annually.

The Gerry Society.—The contest between the State Board of Charities and the Gerry Society (the Society for the Prevention of Cruelty to Children) has reached an acute stage. It will be

remembered that the Board of Charities recently took legal proceedings to compel the Society for the Prevention of Cruelty to Children to submit to its inspection and control. The Society claimed it was not legally subject thereto, and the Court of Appeals sustained its claim. The Board of Charities thereupon introduced a bill into the Legislature bringing that society under its inspectorship. Mr. Gerry in behalf of the Society has privately circulated a letter to certain societies, asking them to write at once, and requesting their colleagues to write to their respective state senators and assemblymen, urging them not to sanction the proposed legislation. This, the Board's officers say, is simply further evidence of an attempt on the part of Mr. Gerry, for personal reasons, to break down and destroy that conservative state supervision which has in spite of such ulterior influence, protected the helpless of the State for over a quarter of a century, and with the support of the people of the State will continue to do so.

Tenement-House Exhibition.—The Charity Organization Society has now on exhibition on Fifth Avenue a most remarkable display of models, plans, photographs, maps, charts, and tables of statistics, bearing upon the general subject of tenement-house life and sanitation. The exhibition is a most striking object-lesson in many directions. The present condition of the tenement-houses of New York is strikingly presented, and the maps illustrate graphically that where overcrowding and filth are there is sickness and disease. The evils arising from the present condition are a distinct menace to the welfare of the community. There are at present over 4400 tenement-houses in Manhattan borough, and new tenement-houses of the most objectionable type are being erected at the rate of 2000 a year. This exhibition is an effort on the part of the Society to place before the public in concrete form a clear and comprehensive idea of existing conditions, so that intelligent action may be taken to remedy them and prevent their multiplication. No more concrete opportunity has ever been offered to the members of the profession, or to the public, to familiarize themselves with the degrading conditions under which decent and respectable working-men and their families are forced to live. The Society is acting wisely in the belief that, when existing conditions are understood and a knowledge of what has been done in other cities to improve similar conditions has been supplied, a thorough and satisfactory remedy will be applied.

PHILADELPHIA.

Health Report.—Deaths in the city for the week ending February 17th were 503, a decrease of 28 over those of the previous week and a decrease of 37 from the corresponding week of last year. Contagious diseases: Scarlet fevere, 93 cases, 3 deaths; diphtheria, 122 cases, 25 deaths; typhoid fever, 76 cases, 14 deaths.

Class Reunion.—The Executive Committee of the Alumni Society, University of Pennsylvania, medical class of '75, is planning to hold a reunion of the class at the coming commencement in June next. Members of the class are requested to send their present addresses and a brief account of their careers since graduation to Charles W. Dulles, 4101 Walnut street, Philadelphia.

Silver Nitrate in Phthisis.—At a meeting of the County Medical Society, February 14th, Dr. T. J. Mays exhibited several patients to show the results following the use of injections of silver nitrate in cases of phthisis. Some advanced cases showed marked improvement after three injections had been given. Five minims of a 2½ per cent. solution were used at each injection. Patients suffering from asthma and bronchitis have also been entirely relieved by this treatment.

Typhoid Epidemic Threatened.—Conditions seem to be ripe for another epidemic of typhoid fever. Last week's health report shows an increase of more than 35 per cent. in the number of cases and more than double the number of deaths of the previous week. The State Board of Health is endeavoring to locate sources of contamination along the Schuylkill river and to ascertain the exact condition of the water. Bacteriological tests are being made to detect the presence of the bacillus coli communis in the river water. Secretary Lee states that the typhoid bacillus is difficult to detect in water, but that the colon bacillus is never present without being accompanied by typhoid germs.

Report Sidetracked.—The results of a four months' investigation of the alleged irregularity in State examinations were presented to the Medical Council of Pennsylvania on February 13th. The result was the following resolutions "Resolved, that the report of the Board of Medical Examiners, together with all the testimony submitted therewith, be received and referred to a committee of five members of the medical council for the purpose of having a thorough examination made of all the facts alleged and testified to, so that a full report may be made to the council, for their subsequent action.

"Resolved, further, that the committee be requested to report what action, if any, can be instituted under the law looking to the permanent correction of the evils complained of."

The committee appointed consists of three lay members—the Lieutenant-Governor, the Attorney-General, and the Secretary of Internal Affairs—and two physicians, both of them members of the Examining Board.

Post-Typhoidal Insanity.—Dr. J. M. Da Costa discussed an unusual case of this affection at the Pennsylvania Hospital February 17th. The patient was a man of 21, who had passed through an ordinary attack of typhoid fever without being delirious or showing any extraordinary nervous manifestations during its course. The temperature became normal the seventeenth day of the

disease. Seven days after this a curious mental state developed, taking the form of a nocturnal delirium of mild type. The patient was confused, failed to recognize the nurses, thought he was being treated wrongly, wished to go to work, etc. During the day there were no hallucinations or confusion and the patient did not remember the delirium of the preceding night. This condition still persisted at the time of the clinic. The case illustrated a type of confusional insanity following typhoid fever, and was stated to be almost alone in the history of the affection in that it occurred only at night. The prognosis was considered favorable because of this fact.

Ligation of Abdominal Aorta.—The findings of the autopsy made upon the body of the patient in whom Dr. W. W. Keen ligated the abdominal aorta were reported February 14th. The ligation was made at a point just below the celiac axis and immediately above a large aneurismal sac. The patient lived 48 days after the operation. The femoral pulse was re-established 24 hours after the ligation and in three days pulsation began in the aneurism.

Autopsy showed the condition to have been one of false aneurism. The anterior wall of the sac was made up of the aorta and the condensed surrounding tissues, the posterior wall being largely composed of the bodies of several vertebræ, these being considerably eroded. The opening in the aorta was on the posterior aspect of the vessel. The ligature, which was composed of four strands of floss silk, had cut completely through the aorta, death resulting from hemorrhage at this point. No clot was present either above or below the point of ligation.

Dr. Keen considers the case as demonstrating the possibility of successful ligation of the aorta under modern aseptic surgery. In any subsequent case he would use a broad ligature of tape or silk ribbon in order to avoid severing the artery.

Laryngological Society.—The annual meeting of the Eastern Section of the American Laryngological, Rhinological and Otological Society was held in this city February 17th. Cases of "Empyema of the Frontal Sinus" were reported by Drs. F. T. Rogers of Providence, R. I., and T. R. Pooley of New York City. The former directed particular attention to the fact that symptoms were referred to the opposite sinus instead of to the one affected.

Dr. A. B. Duel of New York City reported a case of "Empyema of the Antrum of Highmore of 15 years' Duration," with recovery after operation. A fragment of a tooth broken during extraction was the nucleus of a calculus found in the antrum. Various operations and attempts at drainage had been resorted to and during one period of five years the patient had used daily irrigation. The symptoms becoming aggravated the patient sought relief, and a radical operation was advised and performed. An opening large enough to admit a finger was made through the canine fossa, the cavity of the antrum washed out, the calculus removed, the thickened lining membrane curetted, and the cavity irrigated and drained. In four weeks the lower opening had healed.

Dr. Duel advises the opening of the canine fossa in cases of antrum disease of long standing, where the lining membrane is thickened and needs curetting, for the following reasons: 1. It affords an easy and direct means of access. 2. It is the part most favorably situated anatomically for drainage. 3. An opening can be made large enough to admit a finger, to permit curettage, and to allow inspection. 4. It promises a rapid and certain cure. 5. It is not likely to be infected by food, it can be kept open by drainage, and it can be closed by scarifying the soft tissues.

Dr. W. J. Freeman of Philadelphia read an exceptionally able paper on "Rhinoscleroma" and reported a case. The patient is a Russian who has been in this country but a few years. He has no headache, cough, or ear trouble, and his general health is excellent. The nostrils are almost occluded, the uvula congested and relaxed, and the lingual tonsil enlarged and red. The characteristic bacillus was found.

Dr. H. H. Curtis of New York City reported an interesting case of "Primary Epithelioma of the Maxillary Sinus." The patient suffered from neuralgic pain and tenderness was detected, but no discharge was present. The sinus was trephined through the cavity of the last molar tooth. In ten days the nose was involved and the whole jaw tender. A larger opening was made and the entire cavity evacuated, syringed with peroxide of hydrogen and packed daily with iodoform gauze. In two weeks there was difficulty in swallowing, in four weeks the nasal cavities were occluded and a tumor the size of a large apple projected externally. The pain was so intense that five grains of morphia were required each night. The death of the patient occurred at the end of the sixth week.

CHICAGO.

College of Physicians and Surgeons.—This college has procured a lease for its building from the University of Illinois for a term of twenty-five years, at an annual rental of $12,000. The contract provides that the university shall have one-third of the net earnings of the medical school, and the stockholders the remainder.

Filters in Evanston.—The question of a city supplying pure drinking water to its people by putting a filter in each residence in the city was thoroughly discussed recently by the Evanston City Council. The cost of putting in a filter in each house and maintaining it for twelve years would be $72.45, while the rental of each for the same period would be $72.00. University professors and physicians endorsed the use of filters at this meeting. It is believed that a filter will be put in each house.

A Rich Charity Patient.—A few days ago, a charity patient by the name of Sam Besick, sixty years of age, died at the Chicago Baptist Hospital and was believed to be penniless. Money and securities amounting to $5000 were found sewed in his clothing. His tattered coat and waistcoat were literally lined with gold and silver coins. There were fifteen one hundred dollar bills sewed in an inner pocket, and a leather purse containing two hundred dollars was found under his coat collar. The money had been there so long that the coins were worn smooth and the purse was half-full of gold dust.

Visiting Medical Schools.—A committee of Rush Medical College, consisting of Drs. E. Fletcher Ingals, J. M. Dodson, Frank Billings, and Arthur Dean Bevan, headed by President Harper of the University of Chicago, recently returned from the East where they visited and inspected the Harvard Medical School, the new School of Columbia University, and the Johns Hopkins School of Baltimore. It is said that a new building will be erected on the property of Rush Medical College within the present year, provided the trustees can secure enough money to make up the balance needed, and this building will be devoted entirely to lecture rooms and laboratories.

Death of Dr. Edward L. Holmes.—Dr. Holmes died February 12th of pneumonia. He was born at Dedham, Mass., in 1828. He was graduated from Harvard at the age of twenty-one. In 1854 he obtained his degree of doctor of medicine from the Harvard Medical School. Dr. Holmes was prominent in Chicago medical circles from the moment of his arrival in this city in 1856. In 1858 he founded the Illinois Eye and Ear Infirmary. His association with Rush Medical College began in 1860, when he was appointed a lecturer on eye and ear diseases. In 1867 he was given a professorship; in 1890 he was president of the college. He was a member of nearly all of the local medical societies and of the Illinois State Medical Society.

Mortality Statistics.—There were 531 deaths reported during the week ended February 10th. There was a diminished number of deaths as compared with the week before from the following chief causes: Diphtheria, 6; pneumonia, 13; typhoid fever, 5, and consumption, 2. Pneumonia was responsible for 100 deaths, and bronchitis for 35. As compared with the corresponding period of last year, the mortality from typhoid fever was remarkably low, there being but three deaths during the week as against 14 for the period of 1899. Of the 531 deaths during the week, 196 were among children under five years of age, and 106 were of persons over sixty years, a total of 296 deaths at these age periods, or more than 55 per cent. of the total mortality. Two hundred and fifty-two cases of contagious disease were reported.

Chicago Pathological Society.—At a meeting held February 12th, Dr. Alice Hamilton presented a paper on the proliferation of elastic fibers in new growths. The growths examined were benign connective tissue tumors, fibrosarcoma and alveolar sarcoma, carcinoma simplex and scirrhus. In all classes of growths, although not in every individual case, elastic fibers were found in the stroma. These fibers varied in abundance, the number apparently being in direct proportion to the richness in elastic fibers of the organ in which the growth occurred. The fibers could seldom be traced to blood vessels. They were most abundant in epithelial growths which showed a well-developed stroma and were often found in large numbers in rapidly growing tumors. The proliferation of elastic fibers in new growths is not mentioned in any of the text-books on pathology.

Disposal of Sewage.—With the introduction of sewerage systems there is one point that should not be overlooked, namely, discharging the organic wastes of a city on the hand of a sister city down the stream. Sewage, unless it is discharged into a stream of sufficient size to make it harmless by being sufficiently diluted, should be purified. There are several methods of accomplishing this, *viz.*, by broad irrigation, chemical precipitation, intermittent downward filtration, and by a septic tank disposal. As the last mentioned is by far the most economical and gives excellent results it is best adapted to smaller cities. Describing briefly the septic tank, it is an air-tight and light-tight structure, made so as to create the conditions for the growth of the aerobic forms of bacteria. The sewage enters this tank, is acted on by the aerobic forms of bacteria which decompose the organic matter and by the processes of nitrification produce the nitrates and nitrites forming mineral compound which are dissolved by the liquid matter and carried away. The result of this action is that after the sewage passes under several boffle boards and finally discharges over a weir in a thin sheet it is a clear liquid, showing little resemblance to the sewage entering the tank. All that remains in the tank is a harmless sludge devoid of almost all organic matter. This method of sewage disposal, which is receiving much attention in the engineering world, was introduced here by Professor Talbot of the University of Illinois. The State owes much to Professor Talbot, in solving this great problem of sewage disposal so practically and efficiently.

Chicago Medical Society.—At a meeting held February 14th, the subject for discussion was surgical affection of the kidney. Dr. L. L. McArthur discussed the symptomatology, diagnosis, treatment, and prognosis of neoplasms of this organ. Dr. M. L. Harris followed with a paper on renal calculi. He spoke of the etiology of kidney-stones, their experimental production; the influence of bacteria in the formation of stones. He pointed out the analogy between kidney-stones and stones of other ducts and organs; also the difference between primary and secondary

stones. The value of pain and urinary changes in the diagnosis of stone was touched upon. The X-ray and urine-segregator were referred to as diagnostic aids. Finally, he dwelt upon the necessity for operation, methods, and results. Dr. D. N. Eisendrath discussed the pathology of renal neoplasms, their etiology and frequency, the general character of renal growths, methods of extension, relation of renal growths, simple or benign forms, sarcomata and carcinomata, and the relationship of renal growths to adrenal structures. Dr. M. Herzog spoke on the peculiar mixed tumors of the kidney. He said that the kidney is a peculiar organ from a histogenetic point of view. It is preceded by two temporary embryonic structures. It is therefore *a priori* not at all improbable that we may find in it peculiar embryonic inclusions which may become the matrix of tumor formation. Tumors of the kidney are frequently puzzling, and the histology and histogenesis of such neoplasms have formerly baffled pathologists not a little. Among the most interesting of renal neoplasms are the mixed tumors, containing epithelial as well as connective tissue elements. The author advanced the views held as to the origin of these mixed tumors or embryonal renal adenosarcomata, and closed his paper by reciting his own theory as to their histogenesis.

GENERAL.

Influenza in Berlin.—The influenza still continues to gain ground; there are more than 80,000 persons in Berlin suffering from the malady, although there has been a light mortality.

X-ray for Cancer.—It is reported from San Francisco that Dr. J. M. Selfridge of Oakland, after suffering from cancer of the face for twenty-five years, has been cured by X-rays. After three recurrences following operative procedures, Dr. Selfridge last October began a series of applications of the X-ray to the growth; all traces of the cancer have disappeared, but the skin and tissue are sensitive. The exposures are being continued.

Hospital Ship "Maine."—Lady Hesketh, daughter of the late William Sharon of Nevada, is the latest American to take an active part in the hospital ship "Maine." She has enlisted the interest of John Kirkpatrick of San Francisco in regard to the formation of a committee for the Pacific Coast, and has opened a subscription with $500. Her efforts, combined with those of Lady Adair, who recently arrived from London on a similar mission, will doubtless be effectual in supplying the funds necessary to meet the expenses of the "Maine," which amount to $15,000 per month.

Army Surgeons Wanted.—The Medical Department of the Army is in need of assistants in the Philippines. Applications for positions as acting assistant surgeons will be received by the Surgeon-General of the Army at Washington. Applicants must be graduates of reputable medical colleges, and have had practical experience in hospitals or private practice. Men between the ages of twenty-five and thirty-five are preferred. All applicants will be examined as to their physical and professional qualifications for service in the Philippines before they are accepted. Contracts will be made for one year, with the understanding that the approved candidate will remain in service for a longer period if his services are required. Applications should be accompanied by one or more letters from well-known professional men, giving testimony as to character and qualifications. Surgeon-General Sternberg announces that letters designed to produce political effect will injure rather than benefit the applicants' chances.

Demented Soldiers.—A report that 250 demented United States soldiers had arrived at San Francisco and were distributed for treatment led to an investigation by order of Adjutant- General Corbin. The report shows that the actual condition has been greatly exaggerated. The commitments of enlisted men to Government hospitals for the insane by the Secretary of War from May 1, 1898, to the present time shows as follows: Admitted to the hospitals: Regular Army, 134; State volunteers, 70; United States volunteers, 10; ex-soldiers recommitted, 9; a total of 223 men. Of this number there have since recovered and been discharged: Regular Army, 68; State volunteers, 54; United States volunteers, 6; ex-soldiers, 1; a total of 129. There are now under treatment at the hospital: Regular Army, 66; State volunteers, 16; United States volunteers, 4; ex-soldiers, 8; a total of 94 military patients. Of the total number treated at the hospital only thirty-seven men served in the Philippines, and of these eleven have been discharged as cured. There was not a single insane patient among nearly two hundred and seventy invalid soldiers just brought home from the Philippines on the hospital ship "Missouri."

The Plague.—Advices from Honolulu February 2nd state that no new cases of bubonic plague had developed there since January 25th, all detention camps were free from sickness of any kind, and the health officers were under the impression that the plague had about run its course. There were still 7400 Japanese and Chinese in quarantine. The health officials have evidently done thorough work, but it has been at great expense. During the quarantine 10,000 people have been in the isolation barracks and upward of 8000 people have been rendered homeless by the burning of buildings. It is estimated that the expense entailed will exceed $1,000,000; the military establishment alone costs about $1300 a day, and in addition to this guards and inspectors employed by the Board of Health have until lately cost half as much more. For nearly a month the Government supplied the rations to about 1900 persons in the quarantine district. In the promptness and thoroughness of the work the health authorities of Honolulu have certainly set an example for the rest of the world. In connection

with their quarantine work a general raid has been made upon the rats. A day was set apart and every householder was supplied with a package of poison for use in destroying these vermin. The latest reports from Manila state that there have been within the walls of that city 52 cases of plague and 43 deaths. The victims were all Chinamen. The famine and the plague continue advancing their deadly work in India.

Medical War News.—In spite of the extremely complimentary despatches that are coming from South Africa regarding the efficiency of the medical corps, the work is not being done as smoothly at is appears upon the surface. In the camp at Modder River typhoid fever appeared early among the soldiers in the ranks and many of them died of the disease. The outbreak was due to the infected river water. At the same camp a severe form of diarrhea attacked the troops; the stools were very acid, frothy, and of a light-green color, a little blood and much mucus being mingled with the liquid discharge. The malady runs its course in about a week, but leaves the patient very weak. That affection was attributed to the sand storms which have frequently prevailed, lasting from an hour to an entire day. The gritty particles of sand breathed and swallowed are held responsible for the diarrhea. It would seem more probable, however, that the germs contained in the sand have been a more active agent than the irritating presence of the sand itself.

On January 8th a serious fire occurred in one of the barrack-hospitals at Maritzsburg; two wards containing 50 patients, were completely destroyed. Fortunately all the patients were gotten out uninjured. The fire is ascribed to the upsetting of a lamp. It has been found that the khaki suits do not afford sufficient protection for the men when sleeping on the field. It is said that extensive orders for woolen khaki uniforms have been placed with manufacturers. The word "khaki" signifies a color (that of mud) and not a material. The hospital ships afford most refreshing quarters for the sick and wounded as they come down from the camps. The correspondent of the *British Medical Journal* reports that at Durban they are having cloudless, blue skies from week's end to week's end, with now and then a shower of rain to relieve any possible monotony. Cool breezes from the southwest, the fresh salt smell of the sea, and an equable temperature day and night are bringing back to health and strength the hundreds of poor, unfortunate sufferers.

The German Army.—The report of Dr. John M. Woodbury, of New York, late Major and Chief Surgeon, U. S. V., who, during the past summer, as United States Commissioner, observed the maneuvres of the German army in the field with reference to their hygienic, sanitary and medical arrangements, has been made to the Secretary of War. The report covers the ground most admirably, and contains some suggestions that it may be found advantageous to adopt in our own army. Regarding the food, the report says that the quality is excellent and the quantity is sufficient, being one-half pound of meat per day per man, a pound of fresh vegetables, a ration of split peas, or beans for soup, and two ounces of coffee, chocolate or cocoa. Each man carries his own cooking utensils, consisting of a tin cannister, in which his provisions are packed. When the top or lid is removed the bottom may be used as a kettle and the top as a coffee-pot. In the field two men usually mess together, one making soup in the bottom of his cannister while the other makes coffee in his, the tops being used as plates. There are no scraps and there is no waste. In the new equipment his provision cannister is made of aluminum; it is carried on top of the knapsack; there is no haversack. The total weight of each man's equipment pack and piece is sixty pounds. The knapsack is made of horse-hide, with the hair on, and is water-proof; in this the soldier carries one extra pair of shoes, two extra pairs of socks or foot bandages, one brown linen fatigue suit, one overcoat, shaving materials, soap, towel, needles and thread, a lump of tallow, fifty rounds of ammunition, a pound of bread and what conserves he may have issued to him. The shelter tent is rolled and attached to the knapsack. No blanket roll, slung from shoulder to hip, is allowed. There are three grades of sick rations: For the very sick special diets; for those not so ill a soup or stew like heavy broth, containing meat, with rice and vegetables; for convalescents, strong supporting diet of roast or baked meat, with potatoes, onions, etc. The medium sick and convalescents receive an issue of claret equivalent to half a pint of burgundy twice daily; for the very ill spirits may be obtained, but only on the doctor's order. There is no such thing as a sick call in the German army; if an enlisted man feels ill or seems to be unfit for duty it is reported to the first sergeant of his company. If on inspection the sergeant finds the man to be in need of medical care, if the case be in the barracks, he is retained in quarters until the medical officer makes his daily rounds, morning or afternoon; if in the field he is picked up by a hospital bearer and taken to the field hospital. The record is kept by the first sergeant, and the man continues to be borne on the company strength, but as "off duty;" when he is returned he is simply marked for duty on the company books; the time that he has been away is stated as "in the hospital." Tentage is small in amount; requisitioned quarters in the nearest village being always used, the Germans having a saying that their worst quarters are better than the best bivouac. They never use canvas when they can get the tight roof of a house. The feet of the soldiers are most carefully considered, each man's feet being inspected by one of his company officers at least twice a week in barracks and oftener in active field maneuvres. The inspection officer searches carefully for strained tendons, blisters, improperly cut nails or untrimmed corns; at the same time each man's socks and boots are carefully in-

spected as to the condition of cleanliness. The entire body of each man is inspected every thirty days by a company and a medical officer, careful search being made for heart lesions, herniæ, venereal disorders, skin diseases, etc.

CORRESPONDENCE.

FADS IN THE STUDY OF EPILEPSY.

To the Editor of the Medical News:

Dear Sir:—Receiving no reply to my letter of January 23, 1900, asking of you the author of the editorial in the News of January 23, 1900, entitled "Fads in the Study of Epilepsy," I wish to record this protest against what appears to me manifest injustice on your part.

I complain that you, the editor of a presumably fair and reputable medical journal, should open your *editorial column* to an unscientific and undignified personal attack such as the article in question proves to be, thus sheltering its author by the anonimity of an editorial.

Very sincerely yours,
A. P. Ohlmacher, M.D.

The Ohio Hospital for Epileptics,
Gallipolis, O., January 31, 1900.

[We regret extremely that Dr. Ohlmacher should have construed the editorial in the Medical News of January 20th as a personal attack upon him, for such was not the intention. No one carefully weighing the mass of yearly literature upon epilepsy can fail to appreciate that many of the authors do not grasp the epileptic phenomena in their entirety, and, as a consequence, tend to draw unwise and unwarranted conclusions from insufficient data. For the sake of maintaining a reasonable sanity of judgment upon these subjects among those readers of the News who do not give especial attention to the convulsive disorders and their allied neuroses, we consider an occasional *résumé* of epileptic literature essential; we published the editorial in question in this connection. With apologies to Dr. Ohlmacher for the unintentional, possible injury to his personal feelings by the Juggernaut of scientific criticism, we submit that there is no adequate evidence in the editorial in question proving it unfair or unscientific.—Ed.]

KIRKES' HANDBOOK OF PHYSIOLOGY.

To the Editor of the Medical News:

Dear Sir:—In 1896 I had to call attention to the fact that Messrs. Wm. Wood & Co. of New York were publishing an unauthorized edition of Kirkes' well-known "Manual of Physiology."

I have recently obtained a copy of the fifteenth edition of their work bearing date 1899, and having on the title page the names of Mr. Morrant Baker and Dr. Vincent Harris as editors.

The facts are as follows: Mr. Morrant Baker (who is now dead) and Dr. Vincent Harris gave up the editorship of the genuine work four years ago, and even before that time Messrs. Wood never had permission to use their work or their names. Since 1895-6 Professor W. D. Halliburton has been sole editor of the hand-book: he has almost rewritten the work from beginning to end, although Kirkes' name has been retained.

One of the special features of our book is a series of colored illustrations of blood-corpuscles, blood-crystals, etc. These together with many alterations and improvements, both in cuts and text, which have been introduced by Professor Halliburton, have been adopted by Messrs. Wood without any acknowledgment of the source whence they were derived, and in the teeth of a protest by Professor Halliburton and myself (who am the proprietor of the book).

Not only have Messrs. Wood "conveyed" a large amount of Professor Halliburton's original work, but they have also issued their book under the names of Mr. Morrant Baker and Dr. Vincent Harris, who have nothing to do with it.

I think it is but right that I should again call the attention of the American medical profession to this glaring and persistent case of literary piracy, for the present United States law gives me no other redress.

The only authorized and complete edition of Kirkes' Physiology sold in America is that published by Messrs P. Blakiston's Sons & Co. of Philadelphia in conjunction with my firm.

John Murray.

50 Albemarle Street, London, W., February 8, 1900.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, February 10, 1900.

DEFICIENCIES IN THE ARMY MEDICAL STAFF—MENTION OF MEDICAL OFFICERS IN DISPATCHES—DISTINGUISHED HOSPITAL OFFICIALS—ANOTHER LEGACY FOR LONDON HOSPITALS—THE LATE SIR T. GRAINGER STEWART.

The extent of the much talked of shortage in the membership of the Army Medical Corps is being slowly but significantly revealed under the pressure of actual hostilities. The Secretary of War, in reply to a question in Parliament, had to admit that almost half the entire number of officers enrolled were now serving in South Africa, leaving only about 350 surgeons for the wide range of all other foreign stations and barely 110 at home. No less than 161 civilian surgeons were already employed in South Africa, and their number will have to be considerably increased ere long. In other words, almost a third of the army surgeons in the field have been drawn directly from civil practice. Moreover, at home nearly one-half the duties of attendance upon troops in garrison and hospital are being performed by civilian practitioners.

To make matters worse, the militia are now being called out for service, and, as the *British*

Medical Journal points out, the Medical Staff Corps of this arm of the service has, incredible as it seems at first sight, to die out almost completely under the well-known fostering care extended by the War Office over things medical. From 250 officers its numbers have shrunk to 24, thus giving one surgeon to each 5000 men of the force! This deficiency, of course, will have to be supplied almost at once, as the force is being called out for service. The combined Army and Militia Medical Corps has dwindled from some 1300 officers forty years ago to barely 900 now, while the size of both forces and the extent of their distribution have greatly increased. If this be a fair sample of the interest taken in the Medical Service by the War Office, is it any wonder that medical officers bitterly complain of the drawbacks and many unpleasantnesses of their position? That the profession at large are thoroughly aware of the facts of the case and resent the attitude of the authorities is significantly seen in the fact that even now, when a tardy and ludicrously inadequate attempt to fill up the ranks is being made by offering thirty commissions (against a shortage of 400) only 25 suitable candidates have presented themselves! And yet there are hundreds of volunteers for medical service at the front by direct appointment. Evidently radical reforms in the Army Medical Corps will be absolutely necessary before the authorities can bring it up to its full complement again.

The mention of medical officers in the dispatches from the front for distinguished services compensates somewhat for the shortcomings of the military authorities. Within the past week four or five army surgeons have been highly commended in the reports of generals-commanding. General Lord Methuen speaks of the splendid manner in which the battlefield of Belmont was cleared of its wounded as "the most perfect work I have ever heard of in war, reflecting the highest credit upon Colonel Townsend." The triumphs of organization by the same medical officer at Enslin and at Modder River are also praised. General Methuen is so delighted with the care taken of the wounded that he says he is glad to have been slightly wounded himself in order to be able to see personally how skilful and assiduous this service is. Colonel Paget especially mentions Captain Moores, "who, although wounded in the hand, said nothing but continued his duties." General Hildyard commends the good service of Major Ricketts in removing the wounded from Beacon Hill. Finally, in his great speech a few days ago in the House of Commons, in defence of the war policy of the Government, Mr. Chamberlain paid a high compliment to the efficiency of the Army Medical Corps. Cynics, of course, may suggest that both the generals and the Hon. gentleman were only too glad to find some part of the conduct of the campaign which they could conscientiously and safely praise, but the fact remains nevertheless that the value of the services of our profession has at last been publicly and officially recognized.

The same week that sees Conan Doyle depart for the front with the Langman field-hospital will probably witness a member of Parliament starting as manager of the American (Van Alen) hospital. This is Mr. Guthrie Murray, representing the borough of Ban, and he has just bade farewell to his constituents in a speech in which he said that he had months ago offered his services to the Secretary of War in any capacity most useful, and he could conceive of none more useful than this. He had special pleasure in taking part in such a substantial and generous embodiment of American sympathy and philanthropy, whose donor, Mr. Van Alen of New York, deserved the gratitude of the British nation. The cost of the hospital he stated at $100,000. Both this and the Langman hospital are made up of tents especially suited to rapid changes of position, and are going directly to the front for use on, or as near as possible to, the field of battle. The manager of the latter hospital will be Lieut. Archie Langman, the son of the donor.

Rudolph Zunz, a wealthy metal merchant of Wimbledon, has just left an unusual form of legacy to several of the London hospitals. This is a specific allotment of $125,000 for the establishment of a ward in whichever of the hospitals his executors may choose, in memory of his wife. This is to be known as the "Annie Zunz Ward," and a specified life-sized photograph of his wife is to be hung upon its walls. The final residue of his estate is to be used to establish as many similar wards as its amount will permit. As this residue bids fair to reach the handsome sum of $400,000 several hospitals will benefit by this touching and most grateful display of devotion to the memory of his departed wife.

The death of Sir Grainger Stewart removes one of the most brilliant names from the list of the English profession. As years are counted on this side of the Atlantic he died comparatively young, being barely 62 years of age, but when we remember that he was handicapped in boyhood with a cardiac defect following rheumatic fever and consider the mass of valuable work accomplished and roll of triumphs won, we are astonished that even his indomitable spirit should have sustained him so long. Another attack of acute rheumatism still further damaged his heart in 1882, and, as in so many other cases, the beginning of the end was brought about by the influenza epidemic of 1891. This seriously disturbed the cardiac innervation, since which his condition has been almost constantly a source of anxiety to his friends.

His history seems to indicate that the great physician, like other geniuses, is born rather than made, for he was scarcely 25 when he published a paper upon the forms of nephritis, which has passed into classical literature, and at 22 he brought out his great work on "Bright's Disease of the Kidney," which made him famous. Beginning his career in Edinburgh as a lecturer in Materia Medica, he passed from this to Pathology and, after seven years' hard labor and brilliant

results, to Clinical Medicine where he shone for so many years. He was great in everything he touched and a living disproof of the popular sciolist theories about the insanity of genius or even its one-sidedness. His greatest success, however, both as a diagnostician and a teacher, was his power of going to the heart of things at once, disregarding the unimportant symptoms of a case to seize upon the vital, sweeping away all the trivial details of a lecture-subject and bringing out its essentials in bold relief. This and his unremitting and incessant industry, were the secrets of his success. He was as warmly beloved personally as he was admired for his scientific attainments and his loss is keenly felt by the entire English profession.

SO-CALLED PERNICIOUS DYSENTERIC FEVER—ARREST OF DEVELOPMENT AND ITS TREATMENT—SURGICAL TREATMENT OF ABSCESS OF THE LIVER — HYDATID CYSTS OF THE LIVER AND DELBET'S METHOD OF TREATMENT—THE QUESTION OF GLANDULAR INFECTION IN CARCINOMA OF THE STOMACH—MORE UNUNITED FRACTURES HEALED BY THYROID EXTRACT—COURTESY OF CHINESE COACHMEN AND THAT OF FRENCH SURGEONS — EDEMA ANTHRACIS—PLEURISY DUE TO TYPHOID BACILLI—ALARMING DEVELOPMENT OF TUBERCULOSIS AMONG NEWLY ARRIVED COUNTRY PEOPLE IN PARIS—THE PLACE OF CALOMEL IN THE TREATMENT OF SYPHILIS—DESTRUCTION OF THE LARVÆ OF MOSQUITOES.

At the Academy of Medicine, January 2d, LAVERAN discussed a work of Kanellis and Cardamitis of Athens upon pernicious dysenteric fever. These authors state that dysentery and malaria are often found as complications of one another, the anemia and weakness which one produces predisposing to the contraction of the other. Laveran said many facts show that when malarial fever and dysentery coexist in the same individual they aggravate each other. Numerous symptoms which have been atributed to "attacks of pernicious dysentery" may be explained by an attack of malarial fever coming on in a patient who has dysentery. The true nature of such attacks can only be known if the blood is examined. The absence of hematozoa enables one with certainty to eliminate the diagnosis of malaria. Moreover, such a patient will generally not have a history of malaria; the spleen will be found of normal size or even smaller than normal, and the attacks will not yield promptly to quinine as they would if they were of malarial character. The term "pernicious dysenteric fever" ought to be crossed from the list of pernicious fevers. There is no such thing as a dysenteric fever developing directly under the influence of hematozoa, but simply dysenteries complicated by attacks of malaria.

SPRINGER spoke of arrest of development of the child and its treatment. Development may be arrested by dyspepsia, hepatic congestion, insufficient thyroid action due to infectious disease, the abuse of alcohol or food, etc. Among the means which are capable of stimulating the growth of the body he mentioned the removal of the adenoids (useful in certain cases only), Swedish gymnastics, continuous aeration, saline medication, and hydrotherapy. But the most important rôle is played by the epiphysial cartilage of the lower end of the femur. He has proved that in case of arrested development, local excitation of this part will awaken physiological activity and stimulate the growth. Growth takes place by thrusts forward. It takes some time for it to show itself anew after a period of repose. To accomplish these results the knees may be wrapped with compresses wet with bitter saline waters. Friction and massage are also useful, but the best treatment is that by electricity. Galvanic, faradic, and static electricity may all be used with benefit, but a combination of static electricity with faradization of the muscles which surround the lower end of the femur produces the most rapid results. The speaker also alluded to the good effects of decoctions of the cereals on the development of the body and of the waist.

PINARD, January 16th, mentioned an instance of vicious insertion of the placenta. There was a tongue-like process of the placenta which extended from its lower margin across the mouth of the uterus. Other than by this process the placenta was not a placenta previa. When such a process exists it is usually said to be atrophied, but such was not so in this case. On the contrary, it was even thicker than the rest of the placenta.

At the same society, January 23d, LUCAS-CHAMPIONNIERE spoke of the surgical treatment of abscess of the liver. A soldier of Algiers was taken ill with violent pains in the epigastrium, vomiting and a high fever, compelling him to remain in a hospital three months. Eight months later he had a second attack more severe than the first, and aspiration showed an abscess of the liver to be present. After resection of the ninth and tenth ribs posteriorly, the abscess was opened and two liters (quarts) of pus escaped. The cavity was lightly irrigated with peroxide of hydrogen and two rubber drains were placed in it. In spite of the late stage at which this patient came to operation, his complete recovery seemed likely at the time of the report. In opening an abscess of this character it is well, if possible, to avoid opening the peritoneal cavity. While the pus itself may be sterile, it is always a good medium for the growth of bacteria. For incising the liver, a thermocautery is preferable to the knife. It consumes more time but reduces the loss of blood to a minimum.

At the Society of Surgery, January 10th, QUENU discussed the treatment of hydatid cysts of the liver. It seemed likely that a cyst treated according to the method of Delbet, by closure without drainage, must fill up with bile. Some-

times when such a cyst is drained, enormous quantities of bile flow out into the dressings, even although there be no infection; and the reduction of pressure which follows a simple aspiration will sometimes result in a transudation of bile. However, it can be said that the transudation of a serous fluid does not interfere with cicatrization. Quenu treated five cases of hydatid cyst without drainage, applying a simple suture in three instances, and a suture in layers in two. Three times a secondary infection interfered with the recovery, due, as he believed, not to any error in technic but to the transudation into the wound of septic bile. He would not be quoted as an opponent of Delbert's method of suture without drainage, but thinks that this plan should be reserved for simple cases in which the general health of the patient is good, and there is no danger of biliary infection.

HARTMANN said that he had twice operated by Delbet's method with complete success, but thought that it should never be used unless the operator can see every part of the inside of the cyst. If he could not do this he could not be sure that there was not some pocket left which still contained some hydatid material. It frequently happens that an apparently clean cyst cavity will after a few days discharge such material.

GERARD-MERCHANT said that he had operated fourteen times upon hydatid cysts by the usual methods with complete success. Many of the patients were, however, slow in recovering, and he therefore tried immediate suture upon the last patient, but put a drain in the abdominal cavity. This he regretted, as it simply delayed the recovery of the patient and served no good purpose.

POTHERAT said that Delbet went too far in claiming that hydatid cysts ought never to be treated by marsupialization. The evils of this open method of treatment are far less now than they were in the days before antiseptics were known, and it is at present quite possible to treat a hydatid cyst of the liver in this manner, and have it heal up in two or three weeks. The danger of Delbet's method lies in the fact that one cannot be sure suppuration will not follow, no matter how careful he may be in his technic.

DELPET took up the question of glandular infection in carcinoma of the stomach. Here, as with all epithelial cancers, the metastases form rapidly. This ability of the epithelial cells to grow and multiply in the lymph spaces of connective tissue is characteristic. In benign epithelial tumors, such as the dermoid cysts, the epithelial cells live in some sense in an encysted state. This peculiar property of the epithelial cells of cancer has a direct bearing on the parasitic theory of cancer. So far as known the cells of no psorosperm will invade the lymphatic spaces, and, if cancer is due to a psorosperm, it is necessary to attribute to these organisms properties different from any that they are at present known to possess.

TUFFIER said that it is not always possible to remove all the affected glands in a case of cancer of the stomach. He performed a pylorectomy upon a female patient, removing, as he thought, all the infected glands. For two years the patient was apparently cured. Then a further growth of the tumor became manifest behind the duodenum, for which gastro-enterostomy was performed to give temporary relief.

POTHERAT mentioned two additional cases in which ununited fractures were cured by the use of thyroid extract. Both patients had sustained fracture of the leg, and in each the union became complete in from twenty to twenty-five days after the administration of the thyroid extract was begun.

At the annual meeting of the Society of Surgery, January 31st, S. POZZI, the President, in the course of an address told the following anecdote: "Heinrich Heine relates that in China, where two coachmen of the Celestial Empire meet in a narrow road and the wheels of their vehicles become entangled, they do not lose their tempers and swear, but, dismounting, they bend the knee and bow several times, and then together they labor to separate their wheels. When this is accomplished they again make obeisance, remount their carriages and drive on. . . . My dear colleagues, let your learned discussions be at least as courteous as the common conflicts of the Chinese coachmen."

At the Medical Society of the Hospitals, January 12th, THOINT mentioned the case of a shepherd who was bitten by an insect in the upper eyelid. The immediate result was a painless white induration, but the swelling gradually spread over the face and forehead, and became violet. The symptoms were such that the man's death was expected, but he finally recovered. On account of the situation of the trouble no incisions were made, but the parts were simply kept covered with compresses wet with bichloride of mercury solution. The lesion did not suppurate but a dark serum could be squeezed from it, which produced no effect upon animals into which it was injected. Despite this fact and the fact that the patient recovered, the trouble was looked upon as an edema due to anthrax, especially as anthrax existed among the sheep of a farm close by the pasture in which the shepherd was employed.

SOUQUES mentioned at the meeting of January 19th two cases of pleurisy due to the bacillus of typhoid fever. These pleurisies appeared in the first week of the typhoid, and were preceded in one instance by a bronchitis, and in the other by a broncho-pneumonia. The pleuritic fluid in each case was bloody, and in one case it became purulent and afterward again bloody before it was entirely absorbed. Recovery of both patients followed without the performance of thoracentesis. The pleuritic fluid in these cases did not possess agglutinating powers, as has sometimes been the case with fluids similarly obtained. This difference in reaction cannot at present be explained.

Barbier called attention to the interesting fact that two-thirds of the tuberculous patients who applied for relief at the various hospitals and dispensaries of Paris were born not in Paris but in the provinces; and that more than a third of these immigrants to the city had contracted the disease during the first six months of their urban life. As very few of these patients gave a history of tuberculosis in their families, contagion was responsible for almost all of the disease. Doubtless alcoholic habits and bad or insufficient food had made the victims especially prone to infection.

Siredy said that in his observation immigrants from Breton, Savoy and Auvergne were especially liable to contract tuberculosis; and that the unhealthful state of the dwellings in which these people lodged on their arrival in the city was favorable to the spread of the disease.

At the Society of Dermatology and Syphilography, January 11th, Danlos showed a patient who, as a result of syphilitic iritis, had nearly lost his sight. For two years he had been treated in different hospitals without benefit, having received in one of them thirty injections of mercuric biniodide. When first seen by Danlos he had a marked mercurial stomatitis. After two weeks' rest from treatment, injections of calomel were begun, with the striking effect of almost completely restoring the lost sight, although only four injections were made.

Fournier said that calomel in certain cases has a wonderful effect. Certain rebellious lesions of the tongue and larynx and certain cases of phagedenism yield like magic to calomel, although they have resisted all other forms of mercury. But at other times calomel fails under circumstances in which the soluble salts of mercury or the proto-iodide will be successful. Recognizing the terrible pain which is caused by the injections of calomel, one ought to reserve this method of treatment for those cases in which milder measures have failed.

At the Society of Biology, January 20th, Phisalix spoke of the destruction of the larvæ of mosquitoes, a problem which has assumed great importance since it is known that they are agents in the spread of malaria. The best means thus far tried to accomplish this end is the pouring of coal-oil on the surface of ponds. This method has been carried out with success in America, where it has been found that one-half ounce of oil is sufficient to kill the larvæ of a square yard of water. The death of the larvæ is caused by the introduction of the oil into their tracheæ. The most favorable season in which to make use of this means is the spring-time.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Thursday, January 18, 1900.

The President, William H. Thomson, M.D., in the Chair.

Myocarditis.—The paper of the evening on this subject was read by Dr. John H. Musser of Philadelphia. This will appear in a subsequent issue of the Medical News. Dr. Henry Koplik then read a paper entitled "Myocarditis in Infants and Children," which will also appear in the Medical News.

Diagnosis.—Dr. Janeway said that despite all the study that has been devoted to the subject the diagnosis of myocarditis still remains a most difficult problem. It has been said that there is a facies myocarditica, and that the diagnosis can be surely made from the patient's face. Most consultants have seen patients who had been assured by experienced physicians that they had no heart disease, yet who have proved on careful examination to be suffering from serious forms of myocarditis. Some such cases serve to show how absolutely unsuspected the cardiac lesion may remain despite repeated examination. Not long ago a man was seen who had developed some time before, as a consequence of slight overexertion, a good deal of difficulty of breathing. There had been a fire in his store and this had led him to run around a good deal more than he had been accustomed to. Physical examination disclosed to the doctor whom he consulted the fact that there was fluid in his right chest. He was told that he had tuberculous pleurisy and that he must leave this climate. His physician was a distinguished diagnostician who had written a book on diseases of the chest and lungs. The patient's heart was pronounced to be normal. He went to Colorado, but experienced no relief, on the contrary his symptoms became worse. On his return from Colorada he was seen by another specialist who had also done some writing on this subject. He, too, also failed to find any heart lesion. Twenty times his thorax had to be aspirated for the continually accumulating right hydrothorax due to his weak heart action. In another case seen not very long ago there were no murmurs present and no symptoms of any lesion of the valvular mechanism. The heart-sounds were feeble and rather characteristic of the presence of myocarditis. The first sound was short and valvular in character, resembling very much the normal second sound. There was the tick-tack that is typical of a greatly weakened heart muscle. Dilatation could be demonstrated and there was enfeebled circulation. Albumin and casts were absent. Finally, as the result either of brain anemia or of some autotoxemia, the patient became delirious and a neurologist was called in. He found traces of albumin in the urine and said that the whole train of symptoms had been due to

chronic Bright's disease. The case went on to a fatal termination and autopsy was secured. The heart was found dilated and contained a number of myocarditic lesions. There was a thrombus of the left ventricle more than half filling the cavity. This, of course, developed towards the end of the case and showed the reason for the marked disturbance of circulation which preceded death. In two other cases that have been recently under observation, hydrothorax was the primary symptom. The text-books usually say that the hydrothorax due to myocarditis, or to any heart lesion, occurs on both sides. It will often be found, however, to develop on only one side.

Bacilli and Tuberculosis.—In a recent case in which the autopsy showed that here was a syphilitic myocarditis and a periarterial gumma around the aorta, compressing the coronary arteries and so leading to further diseases of the heart muscle, the diagnosis of tuberculosis was made. The main physical symptom on which the diagnosis was based was the presence of a one-sided hydrothorax, which was thought to be a consolidation. After repeated examinations a few tubercle bacilli were found in the sputum and the patient was, therefore, sent to Mexico. After death absolutely no signs of tuberculosis were found in the lungs. There was, however, a distinct heart enlargement consisting of hypertrophy and dilatation with considerable myocarditic degeneration. The case brings up the important question of the diagnostic value of a few tubercle bacilli that may be found after repeated examinations. It is so easy to make some little slip of technic, which, because of their universality, will introduce tubercle bacilli from without, that it is always well to have a single such observation confirmed by further investigation. A distinguished bacteriologist who heard not long ago of a number of examinations having been made in a laboratory for the purpose of finding tubercle bacilli in the blood, the result of all of the examinations being negative, said that he was sorry for the laboratory. Under such circumstances of repeated examination a bacteriological error will almost surely creep into some observation.

Angina and Pseudoangina.—It is a matter of not a little surprise how many experienced physicians are led to make the diagnosis of dyspepsia when the condition is really an angina due to serious degeneration of the heart. A very striking case of this occurred not very long ago. The patient was a physician and the consultant who was called thought that the anginoid symptoms could all be attributed to dyspepsia because they occurred most frequently after a hearty meal. It was apparently forgotten that a stomach distended by the presence of food presses up against the diaphram and through it on the heart and so may hamper the heart action. When the heart itself is diseased, this hindrance of its function may readily set up the series of symptoms that we know as angina pectoris. Very often in these cases it is not so much a mistake of diagnosis, as the disinclination of the family physician to pronounce the case one of serious cardiac degeneration so long as there is any ground to think that it may be only functional in character.

Anatomical Division of Myocarditis.—Dr. Adler said it was the custom not many years ago to divide myocarditis from the anatomico-histological standpoint into interstitial and parenchymatous. In the interstitial form it was the connective tissue lying between the muscle fibers and around the blood vessels which was supposed to be affected. Proliferation took place in these tissues with gradual degeneration of the muscle fiber itself and the production of the large so-called fibroid heart. In other cases it was the muscle fiber itself which first degenerated and then an overgrowth of the connective tissue took place to supply its place as it were. Further experience and careful examination of hearts in various stages of myocarditis show that no such hard and fast lines can be drawn. Even very early in myocarditis both processes, the degeneration of the muscle fiber and the proliferation of the connective tissue, will be found to have taken place. There are some forms of myocarditis, such as the syphilitic, which we know begin in the connective tissue, but degeneration of the muscle fiber itself soon sets in to complicate the process. In fatty degeneration in simple atrophy and in brown atrophy of the heart, proliferation of the connective tissue can be found even at very early stages. Many and many a case of myocarditis is discovered only at the autopsy. Some give no symptoms during life, or, owing to complications, the symptoms are not significant enough to call attention to the heart condition present. One reason for this is that the heart muscle fibers are never entirely and uniformly degenerated, but patches of degeneration occur here and there. The healthy portions of the heart continue the work of the whole heart, although under unfavorable conditions, of course. When no macroscopic signs of myocarditis are present, they may be often found with the microscope. These microscopic lesions will sometimes serve to explain symptoms that were obscure during life.

It is becoming more clear from recent observations that not all parts of the heart are of equal functional value. When certain parts are degenerated there is much more disturbance of function than when degeneration occurs in other parts. When of two hearts one is much more degenerated than the other it may yet retain more of its functional usefulness because vital spots have not been affected by the degenerative process. Dr. Musser has called attention to the fact that the capillary muscles form one of these important parts of the heart. When degeneration occurs in them there is much more interference with heart action than if the same amount of degeneration occurred in the wall of the ventricle. There seems no doubt that the auricles are much more important in this respect than has been imagined. Dehio showed that fibrosis of the auricles is of much more frequent occurrence than was formerly supposed and that it is an extremely impor-

tant lesion so far as regards the functional integrity of the organ. The resultant loss of compensation is more than might be expected from the impairment of function of the auricles themselves. With reference to fatty degeneration of the auricles Delhio's observations have been confirmed and further amplified. Pulmonary edema is especially a result of myocarditis of the auricles. The ventricles may be proportionately more degenerated than are the auricles without the production of as serious symptoms.

Arterial Sclerosis.—Arteriosclerosis is usually considered a result of senility. As observations have become more and more searching, however, we have learned that it may occur also among those who are comparatively young. There are certain individuals who have a tendency to the development of arteriosclerosis in early mature life and who have also a marked tendency to myocarditis. One of the principal factors in the development of this tendency seems to be an abuse of tobacco. Considering how harmless the use of the weed is sometimes said to be, it is wonderful how many cases of early arterial sclerosis are associated with its abuse. Syphilis is another prominent cause of precocious arteriosclerosis. Heredity plays a very important rôle in the matter. In many patients in which distinct arteriosclerosis occurs before thirty years of age heredity will be found to be the main etiological factor. There are families in which at a certain period arteriosclerosis with certain cardiac changes are almost sure to appear. This may not occur before fifty or sixty, but they may occur at much earlier periods in life.

In closing the discussion, Dr. Musser said that he regretted that he had not declared as forcibly as he might have done the fact that myocarditis may exist without presenting the slightest symptoms during life. While the characteristic facial expression of patients suffering from myocarditis is one of the best differential symptoms of the disease, it is by no means always present nor was it his idea to present this symptom as one to be found uniformly. In the cases in which unsuspected myocarditis exists, there occur the fatal pneumonias and the fatal terminations of other infectious diseases in persons whose age and general appearance might lead one to think that there was every reason for them to survive the attack. Dr. Musser said that he was glad Dr. Janeway had called attention to the fact that hydrothorax frequently develops during myocarditis and that it is sometimes one of the first symptoms to which the physician's attention is directed. He was especially pleased that Dr. Janeway should call attention to the frequent existence of unilateral hydrothorax in these cases. Some time ago under the direction of Dr. Musser at the Philadelphia Hospital, Dr. J. Dutton Steele, in an article published in the *University Medical Magazine*, very thoroughly reviewed this subject. In a majority of the cases where unilateral hydrothorax occurs the condition is found to exist only on the right side. Dr. Steele found that this was due to the fact of the anatomical relation of the enlarged auricles to the veins of the thorax and especially of the lungs. The pressure exerted by the auricle on the veins is sufficient to interfere with the return circulation and in this way cause the exudation of serum into the pleural cavity of the left side.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Regular Monthly Meeting, Held January 27, 1900.

The President, Henry C. Coe, M.D., in the Chair.

Pain Pathognomonic of Ectopic Gestation was the paper of the evening and was presented by Dr. Henry C. Coe. It will appear in a subsequent issue of the MEDICAL NEWS.

In discussion Dr. Egbert Grandin said that the symptoms of tubal gestation are by no means so characteristic as might be gathered from reading the account of the condition in the ordinary textbook. A recent case seen by Dr. Grandin will serve as a very good illustration of this fact. The patient entered the hospital with symptoms of chronic endometritis and the history of sterility for a number of years. For the endometritis a curettement was suggested. During the operation the curette slipped away from the doctor's hands with the horrible sensation, which practically every gynecologist has had at some time or other, and which indicates that the instrument has perforated the uterine tissues. In order to be sure that no serious harm was done a laparotomy was performed, when it was found that the curette had only entered the subperitoneal space and had not penetrated the peritoneal cavity. An examination of the adnexa showed that the left tube was strictured at several points. In one of the sacculated distentions of the tube an ovum was found. Chorionic villi were demonstrated microscopically in this so that there was no doubt of the diagnosis. The woman had been married for a number of years. There was absolutely no history of menstrual irregularity. She had no idea herself that she had been impregnated. In fact a feeling of almost hopeless sterility had come over her. The accident of the curette perforating the uterus was really a most fortunate one for her. Had her condition been allowed to progress it is very probable that a rupture would have occurred after two or three weeks and a fatal result would have been almost inevitable. It may have been the existence of the extra-uterine pregnancy which caused the uterine tissues to be so succulent and non-resistant that they were easily penetrated, for no more force was used during the curettement than is usually employed. The case serves to illustrate very well the insidiousness with which extra-uterine pregnancy begins and develops. Despite the clear-cut indications given by the text-books there is no group of symptoms pathognomonic of the condition and none that more than suggest the existence of the

condition. At best, the diagnosis is a surmise and not a settled thing.

Thirty Cases of Extra-Uterine Pregnancy.—Dr. Grandin has seen altogether thirty cases of this condition. Curiously enough, six of them were seen during recent years in consultation with a physician who said some years ago that he had not seen a single case of extra-uterinc pregnancy, nor one in which he suspected the existence to be present, in his private practice notwithstanding all that has been said about the frequency of the condition and the number of cases that were being cited and discussed by gynecologists.

Diagnosis of Extra-Uterine Pregnancy.—In 50 per cent. of these cases there was a history of preceding pelvic disease. Nearly always the Fallopian tube was found at operation to be strictured at one or more points. In 80 per cent. of the cases there was severe abdominal pain. This was practically always colicky in character. One patient described it very vividly as being similar to the pain which she remembered having experienced after eating green apples when young. In many of the cases no coincident enlargement of the uterus could be found even after the most careful bimanual examination, although the textbooks set this down as an almost invariable symptom. Irregularity of menstruation nearly always precedes the occurrence of extra-uterine pregnancy. The normal menstruation lasts four to five days; then a period occurs which lasts only from one to two days, followed by others which last from seven to eight days. The rule seems to be for a relative diminution of the amount of flow to occur, followed by a comparative menorrhagia. In 90 per cent. of the cases there is either amenorrhea or the irregularity of menstruation just described. One symptom seems to be invariable, *i. e.*, a mass can always be found on one side or the other of the uterus, or behind that organ.

Mistakes and Complications.—The most usual source of error is a pyosalpinx, or an ovarian abscess. In eight cases in which operation was done extra-uterine pregnancy had been suspected, but a suppurative condition of the tube or ovary was found to be the cause of the symptoms. In one case they were due to appendicitis. In one patient, a single woman of thirty-eight, who was operated on for multiple fibroid, a pyosalpinx was found on one side and an unruptured tubal pregnancy on the other. Had there been a rupture of the gestation sac in this case diagnosis would have been extremely difficult, as the respectability of the patient was beyond all question. In one case in which after operation a double tubal pregnancy was found, one ruptured and the other unruptured, the patient did not think that there was the slightest reason to suspect pregnancy.

A Diagnostic Sign.—The finding of a mass in the pelvis is the most important symptom of extra-uterine pregnancy. The nature of the pain may lead one to suspect this condition, but the rounded, congested, mass felt in the vagina, with vessels pulsating, and atypical hemorrhage should cause one to insist on an examination under anesthesia. These symptoms always justify a posterior vaginal section if after examination under an anesthetic there still remains doubt. If free blood is found in the peritoneal cavity the diagnosis of extra-uterine pregnancy is practically assured. Operation may then be done from below if the operator considers it advisable, although Dr. Grandin's own preference is usually for laparotomy.

Cause of Pain.—The disputed point as to the origin of the pain in extra-uterine pregnancy has always been a subject of great interest. It seems to be due to hyperdistention of the tube, followed by slight rupture. The whole thickness of the tube may not give way at once, but certain fibers may be torn, and small vessels torn across, and finally, a complete rupture of the tube takes place. This intermittent tearing process seems to be the origin of the repeated attacks of pain. When such pains occur, if extra-uterine pregnancy is suspected, an examination under anesthesia should be demanded.

Appendicitis and Ectopic Gestation.—Dr. Brewer reported a rare combination of these two serious conditions. The patient was admitted to Charity Hospital complaining of a good deal of pain and a mass on the right side was plainly to be felt. The case was thought to be one of pelvic abscess and the course of it for a time seemed to justify that diagnosis. There was some improvement in the symptoms for three or four days and the patient seemed to be going on to recovery although the mass did not lessen in size. One day there was a sudden change for the worse. There were severe colicky pains, the temperature ran up to 103°F. and the pulse to 120. A posterior vaginal incision was made and blood was found free in the abdominal cavity. Laparotomy was done and an extra-uterine pregnancy was found. Rupture had occurred some time before and the extravasated blood had found its way up along the cecum and was firmly clotted. In the center of the clot a ruptured appendix was found. It was the rupture of the appendix which had caused the most recent symptoms and the organ was removed with the tumor of the extra-uterine pregnancy. The patient made a good recovery.

Importance of Pain.—In closing the discussion, Dr. Coe said that he had selected pain as the symptom of extra-uterine pregnancy most worthy of discussion because it was the one on which the most emphasis has been laid. In his experience there has been only infrequently a history of menstrual disturbance except that a period is skipped. Patients usually think that they are normally pregnant. The condition that is most hard to differentiate is incomplete abortion when complicated by tubal or ovarian disease. This has given rise to a series of reported mistakes and always requires the most careful consideration when making the diagnosis. In a recent case a very nervous woman who, after having been married for two or three months, missed a period

and then had a grumous discharge from the vagina. She complained of a great deal of pain. Examination disclosed the fact that there was some enlargement of the tube on one side. A diagnosis of tubal pregnancy was made, but operation showed only incomplete abortion and salpingitis. The tumor is a most important symptom, but alone it can not be held to be of a very great significance. An abscess of the tube or ovary may pulsate in a way that simulates very closely the tumor of an extra-uterine pregnancy. The only way to decide that it is not an incomplete abortion with which one has to deal, is to curette gently, and if decidua are found the diagnosis is settled. To operate and find that the patient is only suffering from an incomplete abortion is a very trying situation in which a number of gynecologists have been placed. The difficulty of the decision is, however, so great that it would almost seem worth while to risk an occasional mistake which, after all, can have no serious consequences than to fail to operate upon a real case of extra-uterine pregnancy until too late.

Anuria for Ten Days.—Dr. Grandin reported a unique case of this kind occurring in his service at the Columbus Hospital. The patient had been weakened by menorrhagia due to the presence of a fibroid tumor. This was of the submucous variety and was so large that it completely filled the cavity of the uterus and rendered curettage impracticable. The patient had a diseased heart, was anemic, and suffered from parenchymatous nephritis. The vagina being very small and the tumor large supravaginal hysterectomy was decided upon. The woman's kidneys being diseased it was decided, although with some misgivings because of the condition of her heart, to use chloroform as the anesthetic. After the patient had been under chloroform for about twenty minutes, the house-surgeon became alarmed and substituted ether. The woman was under ether anesthesia for about one hour and she rallied without any unusual symptoms. For ten days after the operation not a drop of urine was passed. It was thought at first that possibly the ureters had been included in the ligatures, but careful catheterization of these tubes by Dr. Collyer showed them to be patent. For three days nausea and vomiting existed. Examination of the vomited matter, of the perspiration, and of the feces revealed the presence of traces of urea. The patient's intellect remained perfectly clear. There was no headache, no twitching, no visual disturbance, no abdominal pain. At no time for eight days was the pulse tense enough to demand nitroglycerin. Coma set in on the ninth day and at the end of two hundred and forty hours from the time of operation the woman died. The treatment was eliminative, steam baths, colon irrigation with hot salt solution, strychnine in large doses, etc., etc. It required six drops of croton oil to move the bowels at first; after the first movement they were kept freely open with salines. For the first five days the stomach retained nothing. Then the patient asked for some beer; this was given her and was retained. After that she drank about two quarts of buttermilk daily. This, then, was an instance of renal anuria, in other words, entire failure on the part of the kidneys to secrete urine. The only other question is the possibility of the inclusion of the ureters in the ligatures. When the absolutely symptomless course of the case after operation is considered, the absence of pain and of eclampsic seizures, this latter theory fails. Unfortunately, owing to religious scruples on the part of the husband, we were unable to obtain an autopsy. It would be interesting to know if there are any other cases in literature in which such protracted anuria has been observed.

Dr. Wilcox said in discussion that the longest case of anuria on record was one of about six days. It occurred in a woman who was suffering from diffuse nephritis who was operated on for a tuberculous knee-joint. The anesthetic employed was chloroform. As in Dr. Grandin's case, for five days there were practically no symptoms; then coma developed and the patient died.

Dr. Grandin said in answer to a question from Dr. Coe, who suggested that there might have been a lesion of the bladder, that the patient had been catheterized by a doctor or a nurse every four hours and that the bladder had been distended by fluid in order to perform catheterization of the ureters. Under these circumstances it would have been impossible for a leak of the bladder to have escaped notice, so that the lesion in the urinary tract must have been higher up.

Membranous Croup.—Dr. Daniels reported a case of nasopharyngeal diphtheria in which the Board of Health examination failed to disclose bacilli. During the week two other children became ill with the disease which resembled diphtheria very much, as there were extensive membranous deposits in the fauces and pharynx. A subsequent Board of Health examination also failed to disclose the presence of diphtheria bacilli. Notwithstanding this failure the cases were treated with diphtheria antitoxine, and the remedy seemed to have its proper effect. Two weeks after the recovery of the first patient, paralysis of the soft palate developed and then neuritis gradually became manifest in other parts of the child's body. Even certain of the nerves of the eyes were affected so that internal strabismus was noticed. The nerves supplying the cervical muscles were also involved and the head could not be held up straight. The palsy spread downward affecting all the nerves except those of the heart and of respiration. The paralysis is now so complete and so persistently progressive that there seems danger of a fatal termination because of the paralysis alone.

In discussing the case Dr. Wilcox said that death from postdiphtheritic paralysis is extremely rare. Some three or four years ago he had some cases under treatment in which the paralysis was so complete that he feared for the patient's life. Every muscle was lamed except those of respiration and, of course, the heart

muscle. A careful review of the literature of the subject at that time showed that there were only two recorded cases in which death was due to postdiphtheritic causes. In both of these cases the muscles of respiration had been affected with the others. This shows the possibility of a fatal termination, but the rarity of the occurrence serves to demonstrate the fact that there is no serious danger of the affection proving fatal.

REVIEWS.

Essentials of Diseases of the Skin. Series of Question Compends. By Henry W. Stellwagon, M.D., Ph.D., Clinical Professor of Dermatology in Jefferson Medical College, Philadelphia. Fourth edition revised. Philadelphia: W. B. Saunders, 1899.

The work at hand is simply a revision of previous editions. The author has brought it into line with the present status of our knowledge of diseases of the skin by many small but important changes in the text. Moreover, he has added to its comprehensiveness by the description of several of the rarer affections. Otherwise the book remains about the same as its fellows, and continues to maintain the high standard of excellence for which these question compends have been noted.

Microscopy and Micro-Technique. By Albert Schneider, M.D., Ph.D., Professor of Botany, Pharmacography and Materia Medica in the Northwestern University School of Pharmacy. Chicago: Chicago Medical Book Company, 1899.

The microscope has become such an important instrument in the scientific world that a knowledge of its use is included in the most elementary training, and is a *sine qua non* for the expert in any field of natural science or medicine. Books upon its use multiply with the instruments. A very excellent type of guide-book to the beginner in schools and colleges is this neat laboratory manual of 190 pages, with ninety-five illustrations.

It is rather broader in its scope than one might expect, as it treats the microscope, not as a mere machine, but as an addition to the eyes. In it the laws of optics are emphasized with a detail that requires an elementary knowledge of geometry and trigonometry; but the practical working value of the book is by no means diminished by these mathematical considerations, since the technic is very plainly and simply set forth, and in such a manner that a beginner, either by himself or under laboratory instruction, could work out the principles that make him master of the lights and shadows, the refractions and the magnifications that extend the eye into the fields of the invisible.

It is a neat, thorough, and useful book that Dr. Schneider has prepared, and all beginners will thank him for having been so systematic and clear in his introduction to the subject of microscopy. The publishers have contributed their share to the good appearance of the volume. A large number of illustrations, the which, although taken from well-known sources, are excellently chosen, enhances the attractiveness of the pages.

THERAPEUTIC HINTS.

For Scarlatinal Desquamation.—The process can be shortened by three or more days by means of regular inunctions of a mixture containing one part glycerine and nine parts peroxide of hydrogen in fifteen-volume solution, acidulated with 1 per cent. hydrochloric acid. The entire body, except the scalp, is to be rubbed regularly with this mixture from the beginning of disquamation.—*Williams.*

For Dandruff.—

℞ Ac. salicylici 3ss
Chloralis hydrat 3i
Sodii sulphat 3iiss
Aquæ q. s. ad.....℥iv.

M. Sig. External use.

Separate hair, apply a few drops directly to scalp (a medicine dropper will be found convenient), and rub in well, and so on until whole scalp is treated. Do this every night for a week, then every second night for another week, when the head is to be washed with tar soap and the treatment resumed. The head should also be washed before beginning treatment.—*Elliot.*

For Chorea in Children.—

℞ Tinct. ferri malatis.....3ii
Liq. acidi arseniosi.....ℳxvi
Aq. cinnamomi .....℥ii.

M. Sig. One teaspoonful twice a day after meals.—*Freyberger.*

Treatment of Ozena.—*Bommier* recommends the following course of treatment to be carried out by the patient:

Twice a day he is to take a nasal douche of boiled water plus a tablespoonful of salt to the liter, using for this purpose a Weber siphon, elevated about two feet above his head. During the douche he should breathe through his mouth, avoid swallowing, and keep the soft palate raised by pronouncing the vowel a. After the douche the patient is to introduce the following ointment into his nasal fossæ, using for each side a bit of the size of a bean, while holding his head backward:

℞ Menthol .....gr. iv
Ac. borici 3ss
Vaseline alb. .....℥i
Ol. geran. rosat.....gtt. xx.

M. Ft. unguentum. Sig. External use.

VOL. LXXVI. NEW YORK, SATURDAY, MARCH 3, 1900. NO. 9.

ORIGINAL ARTICLES.

A NEW AND IMPROVED METHOD OF ENTERING THE ABDOMINAL CAVITY IN THE ILEOCECAL REGION, WITH SPECIAL REFERENCE TO THE REMOVAL OF THE VERMIFORM APPENDIX.[1]

BY GEORGE R. FOWLER, M.D.,

OF NEW YORK;

PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC, SURGEON TO THE METHODIST EPISCOPAL HOSPITAL, ETC.

IN selecting the site and method of the abdominal incision in operative attacks upon appendicular lesions, or surgical conditions which may simulate the latter, two cardinal points must be borne in mind: First, the parts within the abdomen involved in the intended operation should be brought readily within reach. Second, weakening of the wall of the abdomen must be avoided as much as possible by carrying the incision through the latter, whenever practicable, in the direction of the fibers of those structures upon which mainly depend the function of the abdominal wall in resisting intra-abdominal pressure.

The incision in all cases of appendicitis should be so planned as to include removal of the appendix. In order to accomplish this with ease and celerity the technic demands free access to the base of the organ, or its point of junction with the cecum.

Opinions differ somewhat as to the surface relations and clinical anatomy of the appendix vermiformis. The cecum, in certain exceptional instances, may be located at points distant from its normal location in the right iliac region, but, when normally situated, the relation of this portion of the large intestine as a whole to a fixed point upon the abdominal wall is fairly constant. Attempts to arbitrarily fix the exact location of the base of the appendix in its relation to the anterior abdominal wall, however, have proved futile for several reasons, among which may be mentioned the existence of varying points of attachment to the cecum in different individuals, variations in the width of the cecum, conditions of distention on the one hand and relative collapse of the intestine on the other, and, finally, to the mobility of this part of the large intestine as governed by its peritoneal anchorage. A true mesocecum is very seldom observed.

In my own experience ready access to the base of the organ is secured in the largest number of cases through an incision so planned that its center strikes a point corresponding to the intersection of a line extending from one anterior superior spinous process of the ilium to the other, with a vertical line drawn half-way between the median line and the right anterior superior spine. This differs somewhat from Clado's point, this observer placing the vertical line upon the outer edge of the right rectus abdominis muscle and locating the base of the appendix at the intersection of this with a line connecting the iliac spines. The varying width of the rectus muscle and the difficulty of locating this structure in individuals with a thick layer of fat in the abdominal wall constitutes a valid objection to the use of this as a surface guide. While the base of the appendix may be sometimes found as high as McBurney's point, in my own experience it has been most frequently located at the point I have indicated.

As to the second point: The abdominal wall is made up of structures whose functions in resisting intra-abdominal pressure vary greatly. For instance, the skin, fat, planes of superficial and deep fascia and the peritoneum, singly or combined, contribute but a small portion of the force-resisting qualities necessary to insure stability of the wall. For this we must look to the muscular structures and their aponeurotic expansions, and of these the latter are of the greatest importance. To conserve the integrity of these structures is, therefore, of the highest importance, and, following the rule, section of these should be made in the direction of their fibers in order to favor rapid repair and avoid as far as possible the presence of cicatricial tissue. Of the structures under consideration the most important in this region is that known as the aponeurosis of the external oblique. The importance of preserving intact this structure cannot be overestimated, inasmuch as failure of its incised edges to unite leads to bulging forward of the underlying muscle and the final occurrence of surgical hernia.

The next most important structure is the internal oblique and its tendinous prolongations The part of the internal oblique which concerns us most is that portion which arises from the middle third of its origin from the crest of the

[1] A portion of a paper read, with stereopticon illustrations, before the Associated Physicians of Long Island, at the annual meeting of that body, held at Garden City, June 24, 1899. The material comprising the paper, together with the cuts made from the drawings used for making the lantern slides, and of which the illustrations in this article are electrotype reproductions, was incorporated in the chapter upon operative treatment in the forthcoming new edition of my book upon Appendicitis. The material was placed in the hands of the publishers, but a disastrous fire destroyed the firm's plant, and for a time it was feared that my manuscript had also been destroyed. The latter was finally recovered from the ruins, but the delay incident to the fire has prevented the prompt issuing of the book. The simultaneous publication of Dr. Willy Meyer's article in the *Journal of the American Medical Association*, and that of Professor Weir in the MEDICAL NEWS, under date of February 17, 1900, has prompted me to publish at this time the method which I have employed for several years past and repeatedly demonstrated to the classes at the New York Polyclinic, as well as to those attending my other hospital clinics.

ilium, the fibers of which pass obliquely upward and inward and terminate in an aponeurosis which divides at the linea semilunaris in such a manner as to embrace the rectus muscle, continuing forward and finally to the linea alba.

The transversalis muscle, the most internal of the flat muscles of the abdomen, is placed immediately beneath the internal oblique, its fibers, as its name indicates, passing almost in a horizontal direction. The portion of this muscle which is involved in an incision designed to reach the contents of the iliac region is its upper three-fourths, where its aponeurotic expansion to the linea alba passes behind the rectus, blending with that of the internal oblique to form the posterior lamella of the sheath of the rectus muscle.

Finally, the rectus muscle is to be considered. This structure is of importance mainly because of its function in assisting in controlling the effects of intra-abdominal pressure. Its importance as a surface guide is greatly overrated. In my experience the proportionate width of the muscle varies considerably. That portion which is of especial interest in our present study occupies anywhere from one-third to one-half of the anterior portion of the space located between the median line and the anterior superior spine of the ilium. Its principal interest in the present connection rests in the fact that its sheath is made up of the divided aponeurosis of the internal oblique, this being reinforced by the strong aponeurosis of the external oblique anteriorly, and the tendinous expansion of the transversalis posteriorly, the point where these join before enveloping the muscle constituting the linea semilunaris.

A glance at the nerve and blood supply of this portion of the abdominal wall will be of interest in selecting the site and direction of the incision in operating for appendicular lesions. The eleventh and twelfth intercostal nerves are distributed to the muscles of the abdomen. The last named is so placed as to be crossed by almost all of the usually employed appendicitis incisions. The first named crosses the linea semilunaris in a position to be injured in case it became necessary to extend the original incision in an upward direction in exploration of the region of the gall-bladder. These two nerves constitute the motor supply to the abdominal muscles. The ileo-inguinal and ileohypogastric branches of the lumbar plexus are regarded as purely sensory nerves. The first named, however, sends a filament to the internal oblique. Should the exigencies of the case likewise demand extension of the incision in the direction of the pelvic viscera, the ileo-inguinal branch would be more than likely to be divided.

These branches of the lumbar plexus pass from behind forward upon the transversalis muscle, between the latter and the internal oblique. The nerve structure of special importance in our present study is the twelfth intercostal. This passes from behind forward upon the anterior abdominal wall on a level with the lower margin of the umbilicus, where it describes a gentle curve forward and downward piercing the rectus muscle.

The twelfth intercostal nerve is accompanied by a branch of the twelfth intercostal artery, which is frequently encountered. The deep epigastric branch of the external iliac artery also lies upon the transversalis muscle in this region. It ascends vertically behind and just within the outer edge of the rectus muscle, accompanied by its venæ comites. The efferent branches of the latter join the veins at a more or less acute angle and, unless care is exercised, are apt to be injured in an incision placed parallel with and at the outer edge of the rectus.

Having thus briefly stated the anatomical points upon which may be based an ideal incision for gaining access to the ileocecal region, permit me to bring to your notice a new operative method particularly devised for cases of appendicitis operated upon early in the attack and while the infection is confined to the appendix itself, and for cases in which the operation is performed after the attack, sometimes erroneously called "between the attacks." It may likewise be employed in cases in which the infection is not widespread, for exploring the pelvic organs in the female, and for other operative attacks upon the contents of the ileocecal region. The operation is based upon the same principles as the intermuscular incision of Dr. McBurney, this being, in its turn, based upon the anatomical points just stated. The operation about to be described, differs, however, from that of McBurney in that it gives readier access to the contents of the ileocecal region, and a larger working space of the intra-abdominal manipulation without increase in the size of the external incision. As the incision is carried through the structures of the abdominal wall the most important of the latter are divided in the direction of their fibers, and the important nerves and vessels are avoided, thus inflicting the minimum amount of damage and encouraging rapid repair. As further advantages may be

The incision in the skin.

stated the relations of the three lines of suturing in closing the abdominal wound, and the fact that in suturing the long transverse incision extended beneath the rectus muscle, which really constitutes the important feature of the operation so far as gaining access to the appendicular region is concerned, this portion of the line of union is well protected by the overlying muscle.

Fig. 2.

The triangular-shaped flap reflected downward and outward, and retractors applied. The dotted line shows the site of the incision in the aponeurosis of the external oblique.

The Skin Incision.—The incision commences at the upper rounded prominence of the anterior superior spinous process of the ilium, is carried almost horizontally to the outer edge of the rectus abdominis muscle, from which point it is curved downward and extended parallel with the edge of the rectus for a distance of two and a half inches, or more, as required by the exigencies of the case (Fig. 1). The skin, fat and fascia are divided and the triangular-shaped flap with rounded corner dissected and reflected downward and outward, exposing the aponeurosis of the external oblique.

The Incision of the Aponeurosis of the External Oblique.—A retractor is applied at the lower angle of the wound and another at the middle of the horizontal incision. Traction upon these in the direction of the course taken by the external oblique exposes the latter for a distance of three or more inches, if necessary (Fig. 2). This structure is divided in the direction of its fibers to the extent of its exposed portion, two more retractors applied, as shown in figure 3, and the sheath of the rectus exposed and likewise opened. The rectus muscle and the underlying deep epigastric artery and veins are now retracted strongly toward the median line, the outer edge of the incised aponeu-

Fig. 4.

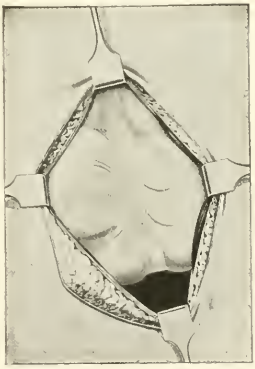
The internal oblique exposed, together with a portion of the sheath of the rectus muscle. The dotted line shows the site of the incision for opening the anterior lamella of the sheath of the rectus.

Fig. 5.



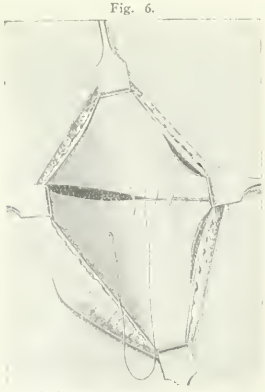
All of the layers retracted and the cecum exposed.

rosis being retracted in the opposite direction (Fig. 4). A space of four inches in its transverse diameter is thus exposed.

The Incision of the Internal Oblique, Transversalis Muscle and Fascia, and Peritoneum.—With the rectus well displaced toward the median line, care being taken to retract the deep epigastric artery and veins as well, and the outer edge of the incised external oblique aponeurosis retracted in an outward direction, the following parts are exposed: In the outer two-thirds of the space between the retractors is to be seen the muscular portion of the internal oblique, this terminating in the aponeurotic portion of this muscle at the point where the aponeurosis divides to enclose the rectus (the linea semilunaris). The inner third includes that portion of the exposed space left by the inward displacement of the rectus muscle, and is occupied by the posterior lamella of the sheath of the latter. In this space the transverse incision is to be made (Fig. 4). For the purposes of this operation the remaining structures of the abdominal wall may be considered as one layer, and the transverse incision carried directly through these in the direction of the fibers of the internal oblique and transversalis into the peritoneal cavity. The incision is commenced at the inner end of the space beneath the rectus muscle and access gained to the cavity of the peritoneum at this point first; after which, with the finger as a guide the section is completed. Retraction of the edges of the transverse incision will be found to give free and ready access to the region of the cecum (Fig. 5).

At the completion of the operation the parts are to be replaced and sutured. The transverse

Fig. 6.

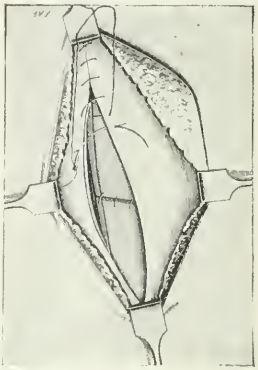


Closing the transverse incision.

incision is closed by a running catgut suture including all of its layers. In closing the incision in the external oblique aponeurosis care must be taken to include in the suture the incised edge of the sheath of the rectus muscle (Fig. 7). The muscular structure itself should not be included in the suture since the interposition of this between the incised edges of the sheath, which may follow the attempts to include the muscle, will prevent prompt union of the aponeurosis.

In view of the supreme importance of securing immediate, firm and permanent union of the aponeurosis of the external oblique it is best to em-

Fig. 7.



Closing the incision in the aponeurosis of the external oblique. The position of the needle shows the method of including the incised edge of the sheath of the rectus in the suturing.

ploy kangaroo tendon for the suture material in the case of this structure at least. Finally, the skin wound is to be closed. This may be done by the ordinary interrupted suture, although this, as all skin incisions, is best closed by the subcuticular suture.

The advantages claimed for this method of operating are as follows:

1. Ready access is gained to the ileocecal region, and ample room secured for all necessary manipulation in the class of cases for which it is designed.

2. Weakening of the abdominal wall and the liability to surgical hernia are reduced to the minimum by (*a*) incising the important musculo-aponeurotic structures in such a manner as to secure immediate, firm and permanent union; and (*b*) avoiding injury to the vascular and nerve supply of the parts involved in the incisions.

AGAIN THE QUESTION OF CANCER.[1]

By ROSWELL PARK, A.M., M.D.,
OF BUFFALO;
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

If one may rely upon medical journals both at home and abroad as fair indices, the problem which most perplexes and interests the medical world to-day is still that of cancer. This must be my excuse for again bringing this subject before you. No better proof of this can be given than the timely appearance of the "Cancer

[1] Read before the Medical Society of the State of New York, Albany, January 31, 1900.

Number" of the *Practitioner,* for April of last year, which aroused the greatest interest all over the world. A year ago I read before this Society a paper on this same subject in which, among other things, I dealt with figures and statistics. The figures themselves were taken from official sources, and, consequently, must stand. Certain conclusions which were drawn from them were challenged. Without permitting myself to be drawn into any controversy upon this aspect of the subject, I simply want to say that such conclusions are purely a matter of interpretation, and that in such deductions a personal element must always largely enter. I put upon them the interpretation which it seemed to me they deserved, with which, however, a few others could not agree. Nevertheless, such as they were, they have been unexpectedly corroborated and confirmed in a general way by writers at home and abroad, all of whom have studied the matter independently. This would-be correspondent of the *Lancet,* making comments upon my paper, drew forth from the editors of that journal a very positive sort of statement, which read as follows: "We may point out as a fact of some importance that Dr. Park's conclusion concerning the recent terrible increase of cancer and the concurrent decrease of tuberculosis in the United States tallies singularly with the experience of this country, and we are surprised that our correspondent, who is avowedly conversant with the literature of the subject, has omitted to notice our own observations to this effect in the *Lancet* of April 22nd, page 1111, and May 20th, page 1376, of the current year. It will thus be seen that in both cases the tendency of English national statistics is to confirm American experience as set forth in Dr. Park's article in the *Practitioner.*"

To go minutely into this subject requires that kind of study of figures and of maps which can only be satisfactorily given at the desk, and it is not my purpose at this time to go into intricacies of this kind. I am perfectly willing, however, to reiterate the essential conclusion which I have repeatedly uttered and published, namely, that cancer as a disease is certainly upon the increase, and that the matter of its *rate* of increase is subsidiary to this principal fact.

When voicing this opinion, as I often have to, I have been frequently asked, "Is not this to be accounted for by improvements in diagnosis?" And some are so sure that the reply to this should be affirmative that they dismiss the whole question with that satisfactory, self-given answer. Such reasoning is, however, fallacious. It is true that improved methods of diagnosis prevail and the disease is now recognized as formerly it was not. It is also true that certain lesions formerly considered cancer are not so considered now; actinomycosis, for instance, and other of the infectious granulomata. This, to be sure, will exclude only a certain small percentage of cases. But one feature of this matter I have never yet seen alluded to in print, and this is that just in proportion as diagnostic methods are improved and operations attempted earlier, just in that proportion do we get actual cures and save these patients from dying of the disease. If, therefore, such improvements be regarded as they should be, it will appear that mortality rates are being actually reduced as compared with the real number of cases. To me this means a great deal, and I do not hesitate to say that it should be a matter of pride with the surgical profession that they may be able to reduce the death-rate, while, nevertheless, the disease rate is slowly creeping up. More important, then, than to study the deaths is to note the number of actual cases of cancer occurring, and I believe that the experience of every surgeon living will tally with my own in this regard.

Aside from the English statistics which I have elsewhere alluded to, which show unmistakable increase in the cancer rate, Verneuil, in 1893, admitted a progressive increase which he determined from a comparison of statistics of succeeding years; while Fabre, in Lyons, writing in 1892, came to exactly the same conclusion.

Concerning the contagiousness or infectiousness of cancer, we have now a number of studies from which it may be determined that in certain limited localities cancer assumes at times an endemic form. Guelliot, and Shattuck and Balance have described it in certain streets; Lucas-Championniere has seen it in villages, Arnaudet has described it in a small *commune* in Normandie, where he seems inclined to ascribe it to the cider which the inhabitants drink and which they do not manufacture in a hygienic way. Fiessinger is disposed to ascribe cancer to some parasite deposited by the bites of certain aquatic insects, while Haviland's views are now quite well-known, as well as those of Noel, who finds cancer in man most common in those localities where cancers in trees are likewise common.

A most cogent plea for collective investigation of cancer has been recently published by Katz[1] of Hamburg. He calls attention to the unsatisfactory explanation afforded by many of the theories now in vogue, and argues logically and convincingly in favor of the method by concerted investigation, and particularly the statistical method. It was Mars d'Espine who perhaps set us our first example in the direction of statistical study, when he reported the statistics for thirteen years in the Canton of Geneva, a careful study which has not yet found a sufficient number of imitators. The special interest of Katz's paper at present for us is the corroboration which his own studies afforded of the statement which I have so frequently made that there is every reason to think that cancer, as a disease, is upon the increase. Katz shows, for instance, from a study of Hamburg conditions, the experience of private practice and the mortuary as well as pathological statistics of the General Hospital there, as well as by the studies of E. Fraenkel, that in that city, especially, there is a well-marked increase in the percentage of cancer. Moreover this statement is accentuated by statistics from all over the

world, which seem to show that not only is the disease upon the increase, but that the age of liability is becoming younger, and that it is rather the better classes of people than the lower in whom it seems to predominate. Katz concludes his paper by a recognition of the difficulty of collective investigation, and at the same time by a statement that it is of the greatest importance that it should be undertaken.

A topographical study of the disease will render great aid in solving some of its mysteries. As classical models for such study we may refer to Power's paper on "The Local Distribution of Cancer and Cancer Houses," in the April (1899) number of the *Practitioner*, the studies contained in the *British Medical Journal*, before July 1, 1899, with the editorial comments thereon, and the paper by Lloyd Jones on "The Topographical Distribution of Cancer," in the *British Medical Journal*, for April 1, 1899.

What could be more accurate, in such work, than Jones' method, which he describes as follows: "Having obtained the list of houses in which persons had been taken ill with cancer, I proceeded to visit the houses and to mark each one on an ordnance map—scale of ten feet to a mile—showing the affected and the non-affected houses in red and black respectively. This map of the borough showed at once that certain districts were fairly free from cancer, while other regions were far more extensively affected. The areas most affected of all showed 1 case in every 2 to 5 houses; the most healthy areas, from this point of view, showed only one case (or no case) in every 60 houses."

The figures obtained were as follows: Total number of houses concerned, 5685; unaffected houses, 5247; affected houses, 438; showing a mean of 1 affected house to every 11.9 unaffected houses. Multiple cases in the same house divisible into: (1) Double cases, 7; (2) triple cases 3.

But as showing what can be accomplished in rural districts in this same line of work, if only the necessary zeal and intelligence be applied to it, take the following illustration furnished me by Dr. John E. Sutton of Albion, Orleans county. He writes me: "During the last five years, or so, there have occurred from all causes, within a range of 1¼ miles of a small hamlet near Albion, N. Y. (Rich's Corners), sixteen deaths. Of these nine were unquestionably from cancer; two were probably caused by cancer, judging from the history of the cases as learned from the friends. Of the remaining five one died of a pistol-shot wound, leaving four of the sixteen as dying of disease other than cancer. There are at present two cases living in the territory mentioned; one of them I operated on a year ago, without recurrence as yet; the other is beyond help." This letter is accompanied by a drawing which makes plainer yet the facts therein stated. I wish that this report of Dr. Sutton's might stimulate many others to similar study and report.

Lloyd Jones, in his paper above referred to, has summarized the views of various observers so succinctly that I reproduce a brief portion of it here: "Briefly, the following are the points which, in each case, several of the most trustworthy authors agree: 1. That cancer picks out certain districts, and that there are areas of immunity and cancerous areas (Shattuck, Noel, Gueilliot, Behla). 2. That immune areas may lie close beside cancerous areas (Pfeiffer, Noel). 3. That malignant disease is most common along the banks of rivers or streams (Pfeiffer, Haviland, Fiessinger, Noel, Nason, Blake). 4. That elevated districts or plateaux are more free from cancer, while low-lying districts carry more liability to its inroads (Pfeiffer, Noel, Haviland, Fiessinger, Nason). 5. That isolated 'cancer houses' or groups of such houses occur in certain districts (Pfeiffer, Fiessinger, D'Arcy Power, Scott, Chapman, Noel, Ogle, Guelliot). 6. That cancer houses often occur near to woods (Fiessinger, Noel), orchards (Fiessinger) or forests of firs (Noel). 7. That persons living upon flooded and clay districts and retentive soils are especially liable to its ravages (Haviland, Butlin). 8. That limestone districts are comparatively free from cancer (Haviland) but do not confer absolute immunity (Butlin). 9. That cancer may be disseminated by means of water (Fiessinger, Noel, Haviland, etc.); that it depends upon the presence of decaying animal or vegetable matter or sewage (Havilan, Noel). 10. Lastly, the suggestion its thrown out by three observers that insects may play a part in the dissemination of malignant disease (Morau, Fiessinger, Noel). Of these three the first is the only one who adduces anything like proof of his assertions."

Durante and Conheim believe that tumors proceed from embryonal remains; Thiersch taught a lessened resistance of connective tissue to epithelial encroachment; Hansemann and Hauser hold to an altered cell condition which they speak of as *anaplasty*; while Fabre-Domergue also believes in certain vague cell changes or cytotrophic alterations; and Ribbert regards tumor formation as unwonted cell activity and the escape of certain cell-groups through proliferating connective tissue. All these statements, however, seem to be rather descriptions of certain facts observed at various times, and they still leave the real question of *why* these cells act as they do quite untouched. It seems quite fair to assume that as a preliminary to cancer formation we must assume a certain *predisposition* of tissues, which may be general or local, inherited or acquired. This is no more than we fully believe to obtain in other diseases to which cancer shows more or less analogy. We see what local predisposition may do under conditions of chronic irritation where we have cancer following chronic eczema, catarrh, ulcers, scar formation, or gall-stone, diseased teeth, mucous patches or other syphilitic lesions, or in the presence of such foreign bodies as clay pipes, soot, paraffin, etc. It is, indeed, now a question whether such irritants as enzymes may not contribute to cancer formation.

Again, in the way of local predisposition we see that nearly all cases of skin cancer occur on exposed parts of the body, face, hands, genitals or nipples; and when on other parts almost invariably on surfaces where there has been some such lesion, such as warts, eczema, sebaceous tumors, ulcers or scars. The only exception to this general statement is the hairy scalp, and yet this may be regarded as, in a sense, a well protected surface. Czerny[2] relates the case of a man whose foot he had to amputate for cancer which grew from the sole. This man had for many years, while a boy, worn a seton in the foot for the purpose of preventing goiter, in accordance with local superstition. It did not protect him from the goiter, which he acquired, and did cause the loss of his foot. If now Ribbert's views concerning disturbed epithelium and anaplasty are correct, why should it have taken twenty years to begin to form a cancer in this case?

Cancer is virtually never seen on the skin of the back save at points which are within easy reach of the hands. When it appears upon the face it is nearly always on those who do not use soap. The exemption of women from cancer of the lip is largely due to the fact that they do not smoke, and that their teeth when diseased fall out much easier and earlier than do men's. Indeed, Czerny's experience is that cancer of the lip is the only kind which is becoming less frequent, and that this is because pipe-smoking is perhaps less the custom, and the people are learning to take better care of their teeth. Cancer of the tongue is also found almost solely in men, because smoking, bad teeth and syphilis of the mouth mostly prevail in the male sex. Cancer of the ear begins nearly always on the upper and outer border, *i.e.*, the least resisting and most often irritated part, as by injury, frost-bite, etc., or else in those recesses which are hardest to clean. Cancer of the upper alimentary tract occurs by far most often at the site of previous lesions or irritations, *i.e.*, scars, fissures, etc. In the stomach and bowel we know that it is often preceded by ulcers. After food has been in one sense sterilized by gastric juice, bile and pancreatic fluid it seldom carries cancer germs, and primary cancer of the small intestine is a great rarity. In the ileocecal region and the colon it becomes common again, and here it is especially that stagnation of the fecal current permits it.

Particularly about the breast and nipple, where chronic mastitis, subinvolution, and ulcers or fissures furnish the local predisposition, do we meet with cancer. Here, also, inherited cell proclivities may play a large rôle. But to external influences must be assigned the major rôle, as well as to such lesions as eczema or intertrigo of overhanging mammæ, or the pressure of corsets. So, too, with cancer of the uterus. Chronic tissue changes furnish the site for most of these lesions, and especially scar tissue, ectropion of mucosa, etc., while cancer of the endometrium is apparently inseparable from catarrhal lesions, placental relics or diseases, etc. Even submucous myomata are accused of giving rise to cancer. The apparently prophylactic effect of circumcision is well known, since Jews relatively seldom get syphilis or cancer of the penis, but gonorrhea often. Cancer of duct glands is relatively common as compared with those of the so-called ductless glands, which latter suffer much oftener from endothelioma and angiosarcoma. The lungs, bones and lymph nodes are practically exempt from primary carcinoma, although not from sarcoma. Summarized, carcinoma takes its origin almost always at those places where chronic tissue alterations or scars have caused local changes which we may fairly regard as constituting a predisposition, or where retention of secretion or contents have produced the same effect.

While all this cannot be said for sarcoma, certain other features stand out predominantly, and are equally significant. For instance, we know other infectious diseases which produce tumors absolutely analogous to sarcomata, even in the possibility of their spontaneous retrocession. Syphilomata, *e.g.*, sometimes bear such a close resemblance to sarcomata that Esmarch was even tempted to think that the latter might have a syphilitic origin. We know, also, how long actinomycotic tumors were regarded as sarcomata. Ulcerating tuberculoma may also be easily and often confused with sarcoma. To this list we may well add Hodgkins' disease, leprosy, lymphosarcoma, certain phlegmons due mainly to streptococcus invasion, or to the micrococcus tetragenus, elephantiasis, rhinoscleroma, rhinophyma and certain skin lesions called by the dermatologists sarcosis cutis, lymphodermia, etc.

It is manifestly impossible to draw any sharp distinction between the true tumors and numerous other infectious lesions, whose parasitic origin is not now denied. We must, moreover, never lose sight of the analogies offered from the vegetable kingdom, where practically all xylomata or three-cancers (many of which are fatal to the trees) are due to invasion of parasites either before or after traumatism of some kind, even such as frost and ice may produce. We must remember that sarcoma of bone, like osteomyelitis, may be apparently produced after injury or exposure, and we can then view it only as the expression of the localized action of some parasite circulating with the blood, and setting up disturbance at the point of least resistance.

Autoinfection with cancer is by no means so rare. Implantation cancer of one labium from the other is not uncommon, and the vagina is not infrequently infected from the os. When colloid, abdominal and ovarian cancers were more frequently tapped than now implantation along the trocar tract was frequently seen. How often we see secondary cancer along the line of incision made for removal of the primary lesion, infected at the time. Czerny says that when asked if cancer is communicable he replies, "Perhaps not; nevertheless, best use extreme caution, destroy the dressings with fire, sterilize the clothing, and avoid common use of utensils, beds, etc." Czerny

relates the case of a woman afflicted with breast cancer who was disposed to attribute it to wearing a corset previously used by an aunt who had died of the same disease.

In the middle of the last century cancer patients were not accepted in numerous hospitals. Because of this fact, Godinot, a priest in Rheims, erected a special asylum for them. But his neighbors protested against such a "pest-house" inside the city, and so he had to remove them in 1778 to a place outside. Not until 1841 were they again received into the Hotel Dieu, and even then they were isolated.[3] Instances must be known to many of you, as they certainly are to me, of various members of the same family, in one house, succumbing one after another to cancer. I have elsewhere called attention to Behla's remarkable study of endemic cancer in the little town of Lückau. There is no doubt but that many fungi can produce certain enzymes which have the power of exciting both cell proliferation and degeneration. So, too, Bejerinck, for example, has found that the juice pressed out from the larvæ of those insects which produce galls in trees has the same power of exciting proliferation of plant cells as have the larvæ themselves.[4]

Czerny and others have recently again raised the question as to the possibility of spontaneous retrocession of malignant tumors. This is a rare phenomenon in which I thoroughly believe, and to which I propose at some later time to devote special time and study. At present I am anxious to obtain data of carefully observed cases, and solicit your aid in securing them. Believing in it, as I am compelled to do, there comes up at once the query, how many cases of improvement after employment of erysipelas toxins or after exploratory operations may be due to it alone?

As already mentioned in speaking of Katz's paper, the number of cases of cancer appearing at what may be called precocious age is being constantly augmented by published instances. For instance, Dufour[5] has reported an epithelial cancer of the larynx in an infant of eight months: Czerny,[6] cancer of the kidney in a child of three and a half years; Kahn,[7] a case of pancreas in a child of two years; Reboul,[8] cancer of the testicle in a child of six and a half; Ganghofner,[9] cancer of the uterus in a girl of eight; Rosenstein, same in a girl of two; Krasnohoff,[10] epithelioma of the lip and nose in a child of eight years; I have seen the same thing in a woman of eighteen; Marjage,[11] carcinoma of the ovary in a girl of eight; Deschamps,[12] cancer of the liver in a child of eleven years; Moore,[13] cancer of the stomach in a child of thirteen; Scheffer,[14] another in a child of fourteen; Hirtz and Lesne,[15] epithelioma of the stomach in a youth of nineteen; and Gangolphe,[16] epithelioma of the lip in a child of 15 years. From other sources I gather the following also: Finlayson[17] has recently reported sarcoma of the stomach in a boy of three and a half years; Scholtz, carcinoma of stomach in a girl of twenty-two; Scheffer, same in a boy of fourteen; Hoffman saw it in a twenty-year-old soldier; Reinbrecht, in a twenty-one-year-old girl; Muth, in a twenty-four-year-old man, and Burger's statistics of 357 cases of gastric carcinoma gave 11 patients under thirty; Olshausen[18] relates cases of ovarian carcinoma in girls aged respectively twelve, nineteen, twenty-one, twenty-three and twenty-nine years. Leopold has had similar experience. Phocas[19] reports 5 cases of ovarian cancer in girls from seven to fifteen. Schröder[20] gives 33 cases of uterine cancer below age of 30 out of 2265 collected, and 22 out of 492 cases that came to autopsy. I have myself seen advanced and hopeless adenocarcinoma of both breasts in a young married woman of twenty-one. Haycock and Bryant have each seen one breast involved in women of twenty-one. In the Greifswald clinic, of 64 breast cancers removed in the last five years two were from patients under twenty-six. Ludlow and Lebert collected 51 cases of cancer of the testicle, of which 5 occurred in boys under five, 1 in a lad of fifteen, and in 11 others the patients had not reached thirty. Some, at least, of these must have been sarcoma.

I have seen sarcoma of the rectum in a patient of seventeen. Marchand has reported rectal carcinoma in a girl of sixteen and Cripps in a boy of seventeen. Billroth saw three cases of intestinal cancer between ages of eighteen and twenty, and Raspe has recorded a case of rectal cancer at age of twenty-eight. Von Bary has described a rectal cancer springing from an ulcus durum at the verge of the anus. Rose and Socin have both operated for rectal or colon cancer at ages of twenty-six and twenty-seven. Cumston[21] has collected several other cases of this same nature and has also reported carcinoma of the liver in a girl of nineteen, cancer of the cervix in a woman of twenty-eight, and rectal carcinoma in a young man of twenty-four. Fabre-Domergue has described an enormous, inoperable epithelioma of the thigh in a man of thirty. Socin operated in 1890 on a woman of twenty-eight for carcinoma of the vulva; Weinlechner on a man of twenty-four for epithelioma of the penis and Rose on a man of thirty for the same condition. It has happened to me to see an unmistakable epithelioma of the penis in a man a little under thirty.

It is never possible to get away from that question of fundamental importance, what is the cause of cancer? Realizing the futility of purely personal effort in the solution of so large a problem, legislative aid was invited and finally secured. By means of this a laboratory has been well equipped and manned for the purpose. This laboratory has been organized in order to study all that the problem includes, and in the broadest possible way. It is not committed to any particular view nor based upon a single idea. As the originator of that laboratory I wish to emphasize that my own papers on the subject, including this one, are not to be considered as anything more than my own personal views, save when so specified. When Dr. Gaylord thinks the time has come to publish the results of his investigations, and

those of his co-laborers, then we may be said—as an institution—to stand committed to whatever views are at that time expressed. For myself, I have not hesitated to espouse the parasitic theory, for many years, and can only see in the labors of others, including those of my colleagues in the State Laboratory, constantly increasing confirmation of my beliefs. Yet these views are as largely the result of clinical as of pathological study.

The parasitic theory in explanation of cancer is that which is to-day most vehemently discussed. It is, however, far from new, for without going back to the views of ancient writers, Harvey[22] wrote that tumors resemble strongly those parasitic productions which we see in the vegetable kingdom, while John Hunter thought that cancer was caused by the presence of an entozoon, and Adams regarded an animal parasite as undoubtedly the cause of cancer. Of late, however, it has taken more particular form and shape, and is being tested by all the canons of modern scientific criticism. Enthusiasts, working under the inspiration of this theory, are easily tempted, however, to lose sight of the tumor side of the question while hunting for the parasite. I have elsewhere gone rather minutely into the arguments which may be advanced in favor of this theory, and, consequently, may be excused in this place from repeating them all. I would say, however, that it is not a question of any one parasite, nor at first whether these hypothetical parasites belong to the animal or to the vegetable kingdom. The primary question is whether cancer is due to intrinsic or extrinsic causes. Those who hold to the views recently enunciated by Ribbert may need again to be reminded of that to which Virchow called attention in his London address, namely, that to endow epithelial cells with all the properties and activities which his theory calls for is to credit them with much greater power than they possess upon their parent soil. It would seem that is is yet to be established that epithelium, leaving its own proper home and migrating, can acquire such enhanced activities as Ribbert would suppose.

Malignant tumors certainly constitute a morbid group which may be regarded as having strong family resemblances, and yet it is quite impossible to suppose that if of parasitic origin a single parasite should be solely at fault. One cannot imagine that epithelioma of the lip and sarcoma of bone-marrow are necessarily due to the same parasite. Here again, as so many times, we find a strong analogy between cancer and the infectious diseases. Suppuration, for instance, we know may be produced by any one of numerous organisms. We acknowledge its parasitic explanation while at the same time appreciating this fact. I want it to be emphasized that in all my own writings upon this subject I have never for a moment asserted all forms of cancer to be due to a single parasite, but believe that there are several, perhaps numerous organisms, which may produce this condition under favorable circumstances. If this be correct, we must first establish the general nature of the process and later try to identify the organism at fault.

When the State of New York by appropriation established a laboratory for the investigation of cancer it devolved upon those who had charge of the work to elaborate a rational plan by which the subject could be properly approached. Necessarily, the first steps in such an investigation had to be taken along conventional lines, and so extensive and yet scattered has been the work of various investigators of the subject that it has required a considerable period of time and no small amount of effort to thoroughly collect and classify the material at hand. It was decided in the beginning that the subject must be as much as possible approached from all sides, but the limitations of our appropriation have thus far rendered it only possible to carry out an elaborate pathological and bacteriological research. From the beginning the plan has been to add to these two sides of the question a complete and full investigation along chemical lines. Aside from the fact that our present quarters and appropriation have thus far not permitted our undertaking this third branch, the proper man was not apparent, and it is only within a few months that such a scientist has been obtainable. In making to you a short report of the amount of work which has been accomplished, I wish to particularly emphasize that much of the work which may at first glance not appear of great importance has been none the less necessary, and has required as great care and precision as work which we are at present conducting and which gives promise of much that is positive. Pathological investigation has consisted in histological examination of tumors hardened by all of the approved and modern methods, stained after various formulæ of different investigators and scrutinized with great care for the purpose of ascertaining to what extent and how constant were the various forms which different investigators have wished to interpret as parasites. We may say in reviewing this portion of the work that early efforts showed that while all of the various appearances described could be found in certain specimens, no method gave constant results. Likewise, we have been able to determine to our own satisfaction that histological investigation alone will never determine the nature of certain suspicious bodies which are to be found in carcinoma. As Dr. Gaylord stated before this meeting a year ago, examination of fresh tumors gave us more encouraging results, and we were able to determine the presence in all carcinomata of certain bodies resembling fat, but which could not be dissolved in ether or other fat solvents. Various attempts to harden and stain these bodies had met with only partial success when we came into possession of an article published by H. G. Plimmer, in the "Cancer Number" of the *Practitioner*. Plimmer had investigated during a period of six years over 1100 carcinomata, and by a special staining method which in principle consists in

using a fat fixative, osmic acid, removing the same by oxidation with hydrogen peroxide, and staining with special reagents, has succeeded in demonstrating the presence in practically all carcinomata of certain characteristic bodies which we now are able to say are identical with those which had been observed by Dr. Gaylord in the fresh state. Plimmer's method furnishes further corroboration of the exceedingly close resemblance which these bodies in the fresh state bear to fat, and it is probable that the success of his method depends upon the fixation of fat-like substances which these bodies contain. Since employing Plimmer's method, Dr. Gaylord has been able to demonstrate in all carcinomata examined the characteristic appearances described by Plimmer. In many cases these bodies are very few in number and only prolonged search will disclose them. Plimmer reports some success in the cultivation of these organisms, and, although we have as yet been unable to obtain the organisms by culture, we are at present working upon an indirect method by which we hope we shall ultimately succeed in isolating the organisms in all cases where present. To indicate to you the fruitlessness of ordinary bacteriological research along old and classical lines, I will give you a short *résumé* of the large number of cultures which have been made in the State Laboratory from various tumors, and the results which these investigations show:

Number of tumors investigated bacteriologically, 42. Of these the results were as follows: Negative, 21; micrococci, 11; fungi, 1; contaminated, 9.

Number of cultures studied from these cases, 1226. (This does not include probably as many more, not recorded, but made and studied from cases ascertained later on not to be neoplasms, and cultures made and studied during the investigation of micro-organisms, especially yeasts and fungi not derived from tumors.) Average number of cultures from each case, 28. Sixty (60) different kinds of culture media were prepared and used in the investigation.

Total number of animals inoculated 118, as follows: (*a*) With fresh tumors, 46. Number of these dead, 32. Average duration of life, 78 days. (*b*) With fluids from fresh tumors or from localities (peritoneum, etc.) containing tumors, 22. Number of these dead, 22. Average duration of life, 73 days. (*c*) With cultures of micrococci or their products, obtained from tumors, 21. (*d*) With fungi, 10. (*e*) With tissues or fluids from animals previously inoculated, as above, 4. (*f*) New work on animals with yeasts, 15. Of which there are living, 9. Of which there are dead, 7.

Cases of tumors investigated histologically, 175. Cases worked out completely, 76. Cases for diagnosis alone, 90. Sections cut, stained and examined, over 2500. Blocks of tissue from animals, cut, 216. Sections examined, over 1200.

In analyzing these figures it will be seen, first, that the inoculation of animals with fresh tumors (46 times) has in no case resulted in the transplantation of carcinoma from man to animal; the animals have, however, in each case perished after an average period of time (78 days) showing symptoms of marked cachexia and with enlarged lymph nodes.

Our most recent work, by which we are introducing tumors into animals, employing another method, has resulted in the discovery of the fact that by the employment of proper staining methods the parasites found in cancer may be detected in large quantity in the enlarged lymph nodes of the experimental animal. This work is still in progress, and we are not prepared yet to publish it in full; but I wish merely to indicate to you the fact that even slight variation in technic may give totally negative or exceedingly positive results. In one case Dr. Gaylord succeeded in producing a true adenocarcinoma in an animal by inoculation with fluid from a soft cancer of the omentum. In this fluid was observed the presence of an organism which apparently belongs in the yeast group, and which we were unable to cultivate. The organism in the original fluid was injected into the jugular vein of a guinea-pig and after three weeks and a half the animal was killed; whereupon minute nodes of beginning adenocarcinoma of the lung were found. This is the first positive case of this kind, and holds out to us the definite hope that when we are able to understand the nature of these organisms we may be able to produce carcinoma in animals with organisms obtained from carcinoma in man. The laboratory is in possession of pathogenic yeasts which various investigators, Sanfelice, Plimmer, etc., have isolated from cancer, and we are now carrying on an elaborate investigation in the first steps of which we have been able to confirm all that Plimmer has published. The principal difficulty which we encounter at present is an entire lack of required knowledge on the part even of botanists of the nature of the organisms in question. These organisms are exceedingly polymorphic, and it requires prolonged experimentation to determine the relation between certain definite bodies found in the tissue, which are presumably these organisms, and the appearance of the same organism when grown upon artificial culture media. In this direction our recent experiments are rendering us great aid, and we have been able to confirm the identity of the bodies described by Plimmer and observed by ourselves in the fresh state, with the organisms which Plimmer has been able to cultivate. In his examination of 1100 tumors Plimmer has been able in only five cases to obtain a culture of the organism upon artificial culture media, indicating that the cultivability of the organism is exceedingly variable. Therefore, the large number of cases in which we have obtained negative results indicates nothing more than the fruitlessness of attempting to study organisms of unknown habitat by conventional methods. There are certain indications that the various forms of tumor are not produced by one

organisms, or even necessarily by one class of organisms. This fact I brought prominently before you a year ago, and to-day I am able to give you definite confirmation of the same, in that from one pigmented tumor we have a pure culture of an unknown fungus, which under certain conditions produces a pigment identical in appearance with the pigment found in the tumor. We have likewise been able by special methods to stain the elements of the organism in the tumor. The experimental portion of our work we are not yet prepared to report upon.

I am quite sure that you will appreciate the difficulties with which we are confronted in the investigation of a subject which has so far baffled science, especially as the organisms which we are forced to study because of their presence in certain tumors, belong to classes with which the pathologist and bacteriologist have as yet had nothing to do, and whose habitat and characteristics are unknown. Only by comparative investigation of all of the species which we are able to obtain, combined with elaborate experimentation upon animals, shall we be able to reach definite conclusions regarding the rôle which these organisms possibly play in the production of malignant neoplasms. Having exhausted conventional methods, we have now entered upon a new field of research, based upon the knowledge which we have been able to acquire of these organisms, and although this work has not been under way for a great period of time I am sure that we have already indications which lead us to believe that the difficulties are not insurmountable.

In this work we have endeavored—and have succeeded to a limited extent—to arouse the interest and cooperation of the veterinarians who come into contact with a large amount of interesting material. To the personal interest of Drs. Wende and Zinc of Buffalo, for instance, we are indebted for some very interesting specimens from animals. Such as these we are always anxious to secure, and, consequently, I would appeal through you to them so far as you have it in your power to spread this request for cooperation.

Medical Societies Exempt.—A bill has been introduced into the New York Legislature exempting from taxation the property of medical societies in cities of the first class.

NOTES ON PLAGUE.

By MAJOR H. E. DEANE,
OF CALCUTTA, INDIA;
ROYAL ARMY MEDICAL CORPS.

(Continued from p. 286.)

My next opportunity occurred in the Bangalore epidemic of 1898-99. I personally treated between November 20, 1898, and February 15, 1899, 568 cases, with a mortality of 50 per cent. At first I had no previous experience to guide me, and had many bitter disappointments, due, I decided later, to my using much too small doses. I used cobra and Lachesis chiefly, and occasionally Crotalus, with six deaths—one case being plague rience, I stuck to the cobra, as easily procurable in this country, and I gave it hypodermically instead of by the mouth. The crude poison of the other snakes could not be obtained in this country, so I had no opportunity of trying larger doses than I already possessed. I treated the last nineteen consecutive cases chiefly with cobra venom from 1/500-1/1000 (solution of the poison in glycerine), in some cases using Lachesis or Crotalus, with six deaths—one case being plague pneumonia. I am acquainted with no such result in unselected cases with any other serum. The treatment may be considered as a serum therapy, the snake venoms being toxalbumins. Although a record in detail is beyond my limits here, I send you the notes. In future I should confine myself to the cobra, and use the rattlesnake in hemorrhagic cases, an instance of which I have never seen.

Case I.—Andaloo (female), age 9. Admitted December 24, 1898. Ill three days with fever, severe rigors, and pain and swelling in right axilla. On admission, temperature 101.2° F.; pulse, 116; respiration, 46. Drowsy; unable to sit up or stand. Tongue coated and red at tip and margins. For the next few days her temperature ranged from 99° to 104° F., pulse 100 to 132. The pain in bubo was very severe. On December 29th she had great difficulty in moving her head; buboes had appeared on both sides of the neck, which increased in size; difficulty in swallowing came on: the swelling increased in the axilla and was spreading down the right arm, with great tenderness of the arm. Up to this time she had been taking naja tripudians (cobra) internally.

On evening of 30th there was difficulty of breathing and swallowing, and I blistered the skin over the swelling on right side of neck (her head was fixed towards the left shoulder), and applied tincture of crotalus (1-1000) to the surface, and gave apis m. v every hour. The next morning the pain was much less, although there was no difference in the size of the swelling. Breathing was easier, and the child had not quite such a distressed look. The swelling of right arm had spread to the elbow and was very tender. Apis was continued every two hours. On December 31st, temperature rose to 104.2° F.; but the next day, January 1, 1899, she looked brighter than she had hitherto been, and there was no danger

as regards interference with breathing or swallowing. The cellulitis of the arm rapidly subsided. On January 3d, it was noted that the swelling was most marked over left angle of jaw. The further progress does not bear on any particular point. The right cervical bubo suppurated, and she was discharged February 14th, quite well.

This treatment seems to offer a great chance of success, and though all cases of plague do not call for it, I feel sure the cure of the fulminating cases will be found in this direction. I may mention that in many cases hyoscyamus has done wonders, and a case in this series will illustrate its action. Let me again emphasize the principle underlying the treatment, namely, a drug having a scientific connection with the patient's condition and then the single drug, alternated, if you like, with another singly administered drug; then and then only can one find out what does good and what does not.

Prevention.—I now come to the most difficult part of the subject, the prevention of the spread of plague. I shall confine myself to the means which have been adopted in India, with the results accruing therefrom. Nothing will be gained by inquiring into the preventive measures in the early centuries and the middle ages, as the results are obvious. During the epidemic mentioned as having existed in Cutch, 1812-1821, endeavors were made to stay the spread of the disease in the Ahmedabad district by preventing communication between infected and non-infected villages, and relations from a non-infected village were not even allowed to attend the funerals of those dying in an infected locality. Orders were issued that any inhabitants of a village who had visited an infected one was to be removed. The measures, however, did not stop the spread of the disease.

During the Pali outbreak, 1836-1838, endeavors were made to stop infection spreading by quarantine, and lines of cordon were established between infected and non-infected areas. The means adopted were ineffectual. When it is remembered how extremely difficult it is to make such a quarantine absolute anywhere, it is not to be wondered at that the system should have been unproductive of good results in a country where the inhabitants were at every device for breaking it. As to the merits of such a system, even if perfect, I will quote the opinion of Dr. Ranken, who investigated that epidemic: "The suspension of the internal trade of conterminous districts, depriving the farmer of a market for his produce, the merchant of the use of his capital, and consequently the laborer of his employment, diminishes or takes away that supply, in the continuance of which the improvident and penniless mass of the people depend to-day for subsistence to-morrow. Nothing, in short, appears to be more calculated than an efficient cordon to assist famine, disease, and with the concomitance of an impure atmosphere, the very infectious or contagious fever which it is intended to eradicate; the combined coercion, restraint and oppression subversive of the functions of society, which the system of quarantine involves, are inferior only to the horrors of plague when it actually prevails."

Again, Dr. Irvine, also engaged in the same epidemic, says: "From what I have myself observed of the plague, it appears that in a small place where only a few cases occur it is very easy to be eradicated; but let the malady once take a firm hold in a large, populous town, to arrest the progress of the scourge will be found in India an impossibility."

To come now to later times, and it will help to an appreciation of the difficulties to be met, to bear in mind the desiderata in combating the spread of any infectious disease, (*a*) early detection of cases; (*b*) discovery of the source of infection and cutting it off; (*c*) isolation of the sick, and destruction by fire or disinfection of articles which may prove sources of future infection. The series of epidemics which have prevailed over India started in Bombay in 1896; the source of the infection and the time of its appearance being unknown. So, two of the important conditions, early detection of cases and dealing with the source of infection, necessary for combating such a disease as plague, could not be fulfilled. When plague was declared in Bombay, on September 23, 1896, it was already prevalent over the city. I will endeavor to state concisely the preventive measures adopted and the results.

1. Efforts were made in the direction of general cleansing of insanitary spots, flushing gullies, lime-washing houses, and disinfecting premises where plague occurred. Result, plague continued to spread.

2. Proclamation was issued that cases of plague were to be segregated, and premises disinfected, if necessary, by force. Result, exodus from the city, riots, and more plague.

3. Eight days later another proclamation was issued, modifying the former one, and no organized attempt was made to segregate the plague cases. Result, plague continued to spread.

4. After the epidemic had passed its fastigium and was on the decline, a Plague Committee was formed, composed of a general, water-works engineer, member of Indian Civil Service, and medical officer in charge of an obstetric hospital, which proceeded to deal with the subject at the point of the bayonet. Houses were compulsorily searched, cases were removed to hospitals, and premises evacuated and disinfected. Result, plague continued to decline.

I held an appointment under this Committee and I can say that Bombay had never had such a cleansing before. The effect on the plague was not obvious; the compulsory measures were instituted when the epidemic was already on the decline, but at all events they promised well for cleansing the town of infection. The health officer of Bombay reports concerning the institution of the Committee that "it was a period of panic and irritation. The measures were followed by concealment of cases, and concealment led to the intensification of the type. The conditions ex-

isted which it would have been necessary to create had it been desired to intensify the disease."

The promises as to the measures destroying the infection were not fulfilled; far from it, The disease began to display activity again in September, 1897, after a lull from July. Search from house to house was again instituted, but as the protecting presence of troops was withdrawn, very serious riots ensued. The system of attempting to get cases reported through Vigilance Committees, composed of influential members of the native communities was then started and failed. The end of it all was that the disease went unchecked and Bombay suffered from a more severe and virulent epidemic and a larger mortality than obtained in the first outbreak. The history was repeated yet a third time, and plague continues in Bombay. I think the lesson to be learned from the experience of Bombay is, what not to do.

The next outbreak with which I was personally concerned was at Bangalore, in 1898-1899. As Bangalore was connected by rail with infected areas in the Bombay Presidency, efforts were made early to prevent the entrance of infection. Inspection of all railway passengers was instituted, with power of detaining all persons coming from infected areas, and removal of plague cases to hospital, and of persons who had been in contact with such, to a segregation camp. The disease came nearer to Bangalore and infected it; and it was reported: "If any lesson is to be learned from the results of these measures it is that plague cannot be kept out of a place by railway, still less by road inspection." The disease broke out in two different localities almost simultaneously. One occurred on August 12, 1898, in the person of a man who had arrived the previous day from Hubli, a badly infected area. On August 13th plague was found in a family near the railway sheds at the station. Supposing that the first related case was a direct importation from Hubli, which is reasonable, there is nothing to show when or how the disease was introduced which affected the second family noted. This family consisted of coolies employed at the railway sheds, but whether the infection was brought by human beings, or fomites, or other means is unknown. The disease at first spread slowly, but by the middle of September was extending rapidly, reached its height in October and November, and in March, 1899, the epidemic ceased.

I will briefly summarize the measures adopted. At first an attempt was made to deal with the disease as had been done in Bombay, *i.e.,* by force; only, forcible house-to-house searching was not carried out. But before the people had experienced any severity, they determined not to have any plague measure at all; an exodus set in; passive obstruction of every kind was practised, and on one occasion active opposition raised. Every device was adopted for concealing cases; corpses were thrown out on the roads, removed into other quarters than those in which they had died, disposed of in wells and tanks, or secretly buried. The people would respond to no inducement to declare cases, and the better class of native offered no help; chiefly, if not entirely, in the former case, from dread of removal to hospital and segregation camp. Men were then placed in charge of districts to get information of cases in any way they could, and it was penal to dispose of a corpse without a medical certificate from a medical practitioner or a Government Medical Officer. At first native hakims were allowed to grant certificates, but as only nine cases out of some hundreds certified by these men were said to be plague, and such unique causes of death as from "perjury" and "the Grace of God" were declared, the permission to certify was withdrawn. Disinfection was carried out, patients found suffering from plague sent to hospital, and those who had been in contact with them to segregation camp. The number of people segregated was out of all proportion to the plague cases, and segregation was an obvious failure. The same thing has obtained all through the history of the disease in India. The difficulty of dealing with the outbreak was increased enormously by desertion and strikes among menial establishments; attendants for the hospitals had to be imported from elsewhere, coolies could not be got for disinfection work, or removing corpses, which had to be left in the houses for considerable periods. The organization was in working order when the epidemic began to decline, and any inferences drawn then as to the effect of improved measures hastening the downward course, I think, are practically valueless. As regards any result from the earlier measures, it was not in the direction of abating the disease, but from the concealment of cases, removal of sufferers from one place to another, indiscriminate distribution of corpses, all owing to dread of segregation, actually contributed to the spread of plague.

The third place in which I have had experience personally of plague is here in Calcutta. Here, again, we are defeated at the outset, the method and time of the introduction of plague being unknown. When I took up the appointment of Medical Charge of the Plague Department, there was no doubt as to the existence of the disease in Calcutta; this was in July, 1899. The early history of the subject, however, is very uncertain. There was a great professional disagreement among the medical men as to the diagnosis of cases; some said they had found the characteristic bacilli in the blood and declaring the patients to be suffering from plague, others equally emphatically denying that the cases were plague. In October, 1896, the Health Officer at the time said he had seen cases of plague which were declared by others not to be so. The former said that the drastic measures adopted by him stamped out the commencing epidemic. It will not be profitable to continue this part of the subject. The first cases about which there was any agreement occurred in March and April, 1898, and by the end of the latter month the disease began to spread. On April

30th plague was declared in Calcutta, and the pronouncement was anticipated by the populace, and a panic set in from fear of prospective plague measures, including inoculation, resulting in an unprecedented exodus from the city, it being estimated that from one-fourth to one-third of the population left. The orders for dealing with the epidemic which were promulgated at the declaration of plague, on April 30th, were the Bombay Rules, house-to-house visitation, segregation of sick and those who had been exposed to infection, etc., but the orders were modified in that they provided for private hospitals and segregation camps for the better classes. Inoculation was recommended, but no suspicion of enforcement was to be allowed. Then followed a period of protest on the part of the populace in the shape of strikes and disturbances; during which a mob burnt an ambulance in the street, murdered an Austrian, who was an object of suspicion as an inoculator, owing to his carrying a hand-bag, and attacked an English medical man on plague duty who shot two men in self-defence. During this time the general health of the town was remarkably good, and there was a prevalent public opinion, shared by the native practitioners that there was no plague at all. This idea is still prevalent and fostered by certain sections of the press and by medical men. The total number of plague cases reported up to the end of July, 1898, was 190; so it will be noticed that the disease had not spread to anything like an alarming extent; and the area in which it was prevalent was comparatively limited and the most crowded part of the town. However, as no compulsory measures were practically put in force to detect cases, it is an uncertainty as to how many cases of plague actually occurred and, had they been enforced, we have seen that they would certainly have failed to attain such an object. The only measures adopted was disinfection of rooms where cases were found to have occurred. Calcutta was declared free on October 10, 1898; the total number of cases reported from August 1st to October 10, 1898, being 40. After October 10th cases of a more or less suspicious nature continued to be found; and in January, 1899, they increased, with no doubt as to the fact of their being plague, and on February 24, 1899, Calcutta was again declared infected.

I remarked just now that during the first outbreak compulsory measures, except as regards disinfection, were practically observed in the breach; and on February 24th, when plague was again declared, what I consider to be the first step in advance was officially taken in dealing with the epidemic in a large city. It was recognized that stringent measures were desirable, but experience in other parts had proved the desirability of modification, and improvements. The resolution issued by the Lieutenant-Governor of Bengal, Sir John Woodburn, ordered that no one should be compulsorily removed either to hospitals or segregation camps. In this way it was hoped that cooperation of the populace would be secured in bringing cases to light. This hope has not been fulfilled; and, with very rare exceptions, the only means of judging the extent of plague is by the system adopted here for the first time, of closely investigating the causes of deaths, from relations and friends. If the case be decided as one of either plague or suspicions of plague, this infection of the premises where the death occurred is carried out; articles destroyed are compensated for, and other articles are disinfected by steam. The only form of compulsion is that this disinfection must be performed; and no material difficulty has been experienced on this point. The people practically afford no help in reporting cases before or after death, even under these mild regulations; indeed, they make investigations into cases very difficult in various ways, which suggest themselves to their ingenuity; but, at all events, we have no disturbances, no strikes, no indiscriminate disposal of corpses; and, what is notable, no alarming prevalence of plague. This remarkable immunity of Calcutta, which, as regards insanitary areas, is enough to please the most fastidious of sanitarians, will be referred to again; but I will say here that I attribute it a good deal to the non-enforcement of compulsory measures, except disinfection. There are rare instances in which a second case has occurred in a room after disinfection, and as evacuation of premises is not enforced, the inhabitants reoccupy rooms perhaps as soon as they are dry, if not before.

History as regards plague in Calcutta, has not been consistently repeating itself. The exact extent to which the disease prevailed in 1898 is unknown, and no good will be gained by quoting figures. The fact which stands out clearly is that although plague obtained a footing, for some reason or reasons, the epidemic has kept within very moderate limits as regards incidence of cases, and this in spite of the fact that the infection has existed over the whole area of Calcutta. I have given one reason to which I attribute this, rightly or wrongly, and now mention other points having a possible bearing on the unique course of the disease in India, here. The population is approximately that of Bombay. The density of population in Bombay in the most crowded areas is from 503 to 670 persons per acre; in Calcutta, from 107 to 276. Cases have been more persistent in the areas here, showing the greatest density of population, 161 and 226 people to the acre. Bombay City is chiefly composed of streets upon streets of many storied buildings, with as many as 1000 to 3000 people under one roof. Calcutta, although in the large bazaar, consisting of high buildings, is also largely composed of bustees, collections of mud and wattle huts, with no second story. Plague has persisted in such bustees where the population has been thick, but I consider that the safety of Calcutta has been contributed to by this construction of the city, each inhabitant having a comparatively large breathing area. The idea has been suggested that the local conditions are not suited for the development of the poison. I suggest that some of the

consideration so lavishly expended on bacteriological suppositions should be devoted to the social and sanitary improvements of the population. We know nothing and can observe nothing as to the likes and dislikes of the bacillus, except through the medium of the human being. There is enough dirt in Calcutta to satisfy any ordinary requirements of any bacillus, but the virulence of its nature is combated by some condition or conditions applying to the human population; and if less attention were paid to the bacillus and its necessary conditions for vitality, and more attention to the human being and his conditions making for immunity or otherwise, we should make more advance. In short, hitherto we have had hold of the end of the stick in the mud with the bacillus thereon; the *man* holding the other end has received scant attention. The condition affecting the man, which I consider to have contributed to the marked immunity of Calcutta is a small population per acre. Whether there are other conditions affecting personal habits, food, or any other circumstances concerning personal hygiene, is a question waiting solution.

I may conveniently here introduce examples of the possibility of stopping an outbreak in a limited population. They occurred in the Bangalore epidemic. A village, inhabited by dhobies (washermen) became infected, and was a source of danger to the Royal Artillery lines close by. A camp was built on an open plain and the people to the number of 543 removed to it. Cases had been occurring daily, and three cases occurred the day after the evacuation. The village was thoroughly disinfected, and the people went back fourteen days later. No more cases occurred. Another village, in a low-lying and unhealthy situation, became infected; and cases persistently occurred. A camp was built on some high ground near, and the people, 1700, removed. Three cases occurred within the five days following evacuation, and there were no more. Such instances show that the opinion as to the plague poison having a great predilection for localities to have good foundation, and are further exemplifications of its comparatively low contagious powers, once overcrowding is stopped, and the people get fresh air and light.

It is a matter of observation that some people have a natural immunity from infectious diseases, but, depending as it must on individual idiosyncrasies in a great measure and to a degree which we do not understand, the property does not help us in the face of a rising mortality in a large city. It is also a matter of observation that there is an acquired immunity in the case of vaccination and smallpox. This became known to us through an observed fact of nature, and not as the outcome of any theory. The principle on which nature works in that process is still a mystery; but we have the fact remaining. Efforts have been made to impart an individual immunity against plague by M. Haffkine, and although I personally think the subject very much *sub judice*, I will give the strongest evidence in its favor of which I am aware. I must first say that any figures dealing with preventive inoculations on Europeans are valueless in my mind; because Europeans in this country have been naturally immune. The few who have been attacked were particularly liable; only what might have been expected from the state of their health.

Preventive Inoculation.—M. Haffkine's fluid consists of plague virus cultivated in broth, the bacilli killed by heat, the broth and the dead bacilli being injected. The preventive results were carefully observed, under favorable circumstances for investigation, at an outbreak in Damaon near Bombay in 1897. The period of observation extended from March 26th to the end of May; 2197 persons were inoculated, and it was estimated that 6033 remained uninoculated. Among the latter there were 1482 deaths, a mortality of 24 per cent.; in the former there were 36 deaths, a mortality of 16 per cent.

In cases where inoculation has been practised, it has been done mostly when the epidemic was declining, and to take one instance, that of Poona, it is reported that no cases occurred in the hospitals among those inoculated; but that the inoculation took place during the decline of the epidemic, and in persons who were not living in highly infected localities, nor belonging to the classes that had chiefly suffered from plague. There is no definite idea as to the length of time immunity is conferred, and to induce a large population to try the experiment in this country is impossible. Any idea or suggestion of inoculation is enough to create panic or riots. Personally, I think the subject in too tentative a stage at present to justify authorities even strongly recommending it; and would in preference advocate an extension of the means we know to confer an immunity, *viz.*, light, air, food, and plenty of them.

In conclusion I will briefly review the lessons to be learned from Indian experience of plague and the difficulties to be contended with. The lesson which stands out in large letters is that the compulsory measures attempted have failed to have the desired repressive effect on the disease, because the populace have, to a man, been dead against them and the authorities. Governments of various provinces, instead of having the people with them, have had to combat opposition of all sorts, as well as devise means of fighting the disease; and the plague plus the inhabitants have won the day all along the line. Any measures to be really effective must carry the people with the Government. I may say at once that such measures have yet to be devised. The utmost consideration which is shown to the people here in Calcutta has failed to enlist them on the side of the Government in the direction of detecting cases of plague, or inducing them to report sickness of any kind. I think this may partly be accounted for by distrust as to what stringencies may be imposed on them, should the epidemic attain more formidable proportions. On the other hand, there is the initial dislike to being inter-

fered with in any way; and it must be remembered that Occidentals, as well as Orientals, dislike their sick being removed to hospitals and their homes disturbed. The main line of objection to plague measures has always been a dread of segregation, with separation of members of families; and Government orders that no wife would be separated from her husband, or a mother from her children, have not succeeded in inspiring confidence. The people display an absolute apathy and indifference to plague, as a rule, but let the Government suggest means by which they may be spared the affliction and a panic ensues. Cases of illness are concealed with every ingenuity, and each one vies with his neighbor in giving false information. Violation of caste is made an excuse for objection to any preventive measures, such excuse having no foundation. Facilities have been given for the institution of private and caste hospitals, but no advantage has been taken of them. Ignorance, distrust and prejudice have held their sway, supported by superstition. Stories have been current that the British Raj is on the wane and that the Queen wants so many hundreds of heads to appease the adverse Fates. The better class of the native communities have been unresponsive to calls for assistance in allaying fears and too often have been the cause of fostering agitation both of an overt and covert kind. It is said in one Government report, "exuberant offers of moral and material assistance were received, but with the increase of the disease further cooperation was withheld, and it is a noticeable feature of the outbreak that Government officers were at no time afforded real and effective unremunerated assistance by any of the inhabitants. The tendency was rather to take advantage of the difficulties that arose for the purpose of private advantages and enrichment." Stories are set about that people are killed in the hospitals. The medical practitioners afford little or no help in reporting cases for fear of losing practice, and, moreover, falsely certify as to the cause of death, perhaps, we will charitably suppose, from ignorance. There is no registration of deaths in India, a fractional part of the population only being sure of any sort of medical man; consequently any cause of death which suits the fancy of a relative is entered at the burying ghat or burial ground. These difficulties need not be multiplied. The whole question is a medico-political one, in which medicine has to be subservient to policy. Medicine says, detect and deal promptly and decisively with the first cases; policy yet awaits a solution as to how to do that. Until that be solved I have no doubt that the policy obtaining in Calcutta at present is the best yet promulgated; get the population against Government as little as possible, provide a hospital for sick if they want to utilize it, if not, leave them alone, carry out disinfecting measures with a minimum of irritation, employing European medical men to supervise everything. One last word, as a guide for the future. Devote some of the labor and attention bestowed on the microbe with such unproductive results to the human being, who is the chief object concerned. Erection of light, airy habitations to replace filthy hovels, and total abolition of dirty, overcrowded areas will do more to stamp out plague than all the bayonets of the British Army. This takes time; time, moreover, counted not by months or years, but by generations. If the money spent on plague operations in India since 1896 had been expended even to half the amount, on improvements in Bombay City before the disease appeared, what a different tale there might have been to relate.

CLINICAL MEMORANDUM.

THE XIPHOPAGES, ROSALINA AND MARIA.

Through the courtesy of the editor of the *Scientific American* we present the following account from its columns of the recent effort that has been made at the Hospital Misericordia of Rio de Janeiro, by surgical procedure to separate these remarkable twins. The operation was undertaken by Dr. Alvaro Ramos, an abstract of whose report was furnished the *Scientific American* with the accompanying photograph and radiograph.

The Xiphopages, Rosalina and Maria.

"After the completion of the physiological experiments which proved the functional independ-

ence of the system of Rosalina and Maria, I still had considerable doubts as to the nature of the tissues constituting the union of the two trunks, and as to the organs that might be found there.

At the last radiographic exposures, which formed the experiments of Roux and Balthasar, strong doses of hyponitrate of bismuth were administered to the two girls, and owing to its opacity to Roentgen rays, this substance was revealed in the stomachs and in some of the intestine coils, thus proving that there is no connection of these organs in one abdominal cavity with those in the other.

Although I was much encouraged by this result, I still had no certainty as to the (possible) union of the livers, a point which could not be cleared up by the radiographs and to which my attention had always been directed, not only on account of the published results of five autopsies in similar cases, including that of the celebrated Siamese twins, but further for terato-genetic reasons.

After making up my mind to try an operation, I diligently took all possible precautions, in order that, if the desired result could be attained, the unsuccessful operation should at least have no disastrous effect. I proposed to begin with laying open the abdominal cavities; then to ascertain if all their organs were completely separate; and, finally, if the possibility of a complete separation was demonstrated, we should cut the cartilaginous ligaments which are at the base of the ensiform appendices and of the false rib; by preserving these ligaments until the end, we should insure the healing of the operative wound notwithstanding strains, in the event the operation could not be completed, as unfortunately turned out to be the case.

After fitting up two operating tables and the necessary appurtenances, and distributing the implements, Drs. F. Fajardo and Miguel Pereira were intrusted with chloroforming Maria, and Drs. Miguel Couto and Antonio Leao with chloroforming Rosalina. Fifteen to twenty minutes later the two sisters were perfectly anesthetized and laid on the first table—Rosalina on the right and Maria on the left; the side on which the thoraces were sunk in most was on top.

I began the operation by an incision of about six centimeters in the skin of the abdomen of Rosalina, a curved incision with the concavity facing toward Maria, distant, at the half height of the connection of the two bodies, about three centimeters from the median line.

Radiograph of the Xiphopages Rosalina and Maria.

The skin having been folded over toward Maria, I found on the median line of the connection the separation of the two recto-abdominal muscles, the right one of Maria and the left one of Rosalina. After moving these aside, as well as the aponeuroses, I first met the fat pre-peritoneal tissue, and then cut through the peritoneum common to both cavities. This opening I enlarged by continuing the initial incision downward four to six centimeters, to the lower end of the connection, leaving the umbilicus on Maria's side. It then became easy to recognize the separation of the intestines and of the stomachs, and to thus confirm the result of the radiographic experiments of Roux and Balthasar.

Turning then my attention to the upper part of the incision, I discovered at once that her heart was not directed toward the right, confirming my previous opinion, founded upon the difficulty of auscultation on the left-hand side, and upon the entire absence of the kick of the apex.

Immediately below the diaphragms were the livers, united by the left lobes, which appeared to form a single body common to both livers, each of which had its particular gall bladder. At the height of the central line there was a suspending ligament, which, from its attachment to the connecting cartilage of the two ensiform appendices, extended to the common chamber of the two livers. In the hope that this ligament might be continued through the parenchyma of the livers, thus forming a septum separating the two lobes, I made an incision in this part of the common chamber, and, instead of finding a septum, I ascertained the continuity of the parenchyma.

I cannot indicate definitely the relative positions of all the other viscera, since the positions had partly been changed. I confined myself to ascertaining the extent of the surface connecting the two livers, and putting my right hand around them, with the fingers in contact with the lower or concave face, and the thumb over the convex top surface, I estimated that the surface to be cut would be about ten centimeters in length and three or four centimeters in width, corresponding to the thickness of the lobes at this point.

Such an operation with all the preparations for insuring hemostasia and the safe replacing of the livers in the abdominal cavity, in accordance with the latest methods of resection of the liver, would certainly require a considerable amount of time. This, added to the time already spent on the investigation, was more than these tender organisms could be expected to resist successfully, and every minute still further reduced their vital energy. I concluded to procede no further. The wounds were dressed in the usual way, and after being awakened without difficulty, the two little girls were soon pretty lively and did not exhibit any great prostration, it being remembered that the loss of blood was very small, since not one hemostatic ligature was required.

Thus the double investigatory laparotomy was fully crowned with success. While I did not achieve what I had hoped I might possibly be able to accomplish, I have at least the satisfaction of having, without injury to the patients, ascertained the conditions of the problem, the best solution of which we have to seek. With surgical methods now known, the separating operation would have a fatal result unless there should be found a method of reducing the parenchyma connecting the two livers, or unless, at least, such a reducing or regressive process should be brought about by some mechanical means.

Pharmacists Protest.—The Manhattan Pharmaceutical Association protests against the bill before the Legislature requiring poisonous mixtures to be placed in bottles of special design.

MEDICAL PROGRESS.

Therapeutic Application of Moist Heat.—Although dry heat can be borne in very much higher degree than moist heat, yet it is almost universally recognized that moist heat accomplishes far more therapeutically with lower temperatures than does dry heat with higher ones. Hugo Davidsohn (*Berlin klin. Woch.*, Jan. 29, 1900) says that the various applications in vogue for obtaining therapeutic effect with moist heat are the local steam or vapor baths, the Priesnitz and the cataplasmic methods. These last two methods are distinguished from each other in their effect, according to Quincke and Solomon, in that the Priesnitz applications affect only the superficial tissues, while a hot cataplasm of happy consistency stimulates the deeper tissues. There are two conditions limiting the application of these cataplasms, first, the degree of heat which various patients can bear and, second, the material out of which the cataplasm is made. As far as the first point is concerned the author says that he has known patients to bear comfortably a temperature of 117.5° F., while others are very sensitive to a temperature of 104° F. As for the material out of which the cataplasm is made, it is necessary that it have the requisites of being very plastic and that it is a poor conductor of heat. The substance best fitted for this is the mineral earth known as Fango. In addition to these advantages this substance is odorless, it does not decompose and, therefore, saves the skin from disagreeable maceration. In order that the patient may be treated with a higher degree of heat than he at first can bear, it is advantageous to subject him for an hour or two to constantly increasing temperatures when a surprising degree of tolerance is attained. This regulation of the degree of heat can be managed by an arrangement of the author's, which he calls a coil-mattress and coil-pillow. As the name implies, it is simple a series of coils or rubber tubing, simulating Leiter's coils, attached to a mattress or pillow which may be applied to any part of the body. This is supplied with water at the requisite temperature by a simple, portable arrangement.

Addison's Disease.—H. J. Campbell (*Quarterly Med. Jour.*, Feb., 1900) after noting the fact that about Halifax he had observed a number of cases of Addison's disease, discusses some of the more important features of this affection, more especially recent experimental work done with the suprarenal glands. The prominent symptoms of the disease, asthenia, muscular weakness, low blood-pressure, feeble cardiac action, headache, vertigo and the gastro-intestinal symptoms may all be explained, in large part at least, by the lack of the normal internal secretion of the suprarenal gland. Experiments of Langlois, who found that the disastrous results following removal of the adrenals might be averted if but one-eleventh of the gland is allowed to remain, also point in the same direction. The explanation of the pigmen-

tation is a more difficult matter. The author believes that it is a reaction, protective or conservative in its nature. From the therapeutic side, cod-liver oil, arsenic, and protection from cold, offer the best general means for treatment. From a theoretical point of view the use of suprarenal extract should give good results, but up to the present time its efficacy has not been definitely proven. This lack of action is probably related either to some defect in the mode of preparation, or more probably to the method of administration. Administration by means of the mouth has given very irregular results and the experience acquired by ophthalmic practice has demonstrated how readily the extract may be altered and rendered worthless. The ideal mode of administration would be by intravenous injection in very small doses, but this is impracticable for continued usage. The mode of administration recommended is by the rectum, in the form of suppositories made up with a neutral fat. The amount required is very small, and it would probably suffice to administer a suppository night and morning over a long period, with occasional intermissions. The frequency and the dose would vary with the individual and should be determined by experience.

Lateral Ureterorectal Anastomosis.—Dr. Reuben Peterson made the following communication to the Chicago Academy of Medicine: "At a former meeting of the Academy, during the discussion of Dr. Lydston's paper, I referred to some recent experiments I had been making in uniting the ureters with the rectum. The ureters were passed under the muscle for a short distance and then made to penetrate the mucosa, various methods of suturing being employed to secure union between ureter and bowel wall. Infection of the kidneys, as shown by bacteriologic and microscopic examinations, occurred in all the animals that recovered from the primary operation. It was found that the infection in nearly every instance was proportionate to the amount of stricture of the ureters entailed by the operation. Thinking that ureteral stricture and subsequent hydronephrosis, by slowing of the stream of urine, might offer increased facilities for the passing upward of the colon bacilli, I set to work to devise an operation whereby ureteral stricture could be avoided. To those who have endeavored to unite the ureter with the rectum by passing the former through the wall of the latter, it is evident that owing to the compressibility of the ureteral wall and the excessive muscularity of the rectal wall, it is only a chance if stricture does not take place, either at the time of, or subsequent to, the operation. Hence, the two organs must be united by a lateral anastomosis if stricture is to be absolutely avoided, because here the opening can be made as large as required.

"With the assistance of Dr. Connell I finally succeeded in making a lateral anastomosis between ureter and rectum, employing a modification of the right-angled suture. The first few animals died because I failed to cover the line of sutures with peritoneum. This is necessary because the ureter cannot be safely punctured by the needle as can the gut wall, and must be protected by peritoneum for fear of subsequent leakage of urine into the peritoneal cavity. For this reason I do not believe the operation devised will ever be practicable for the human being, the danger of leakage even when the sutures are well protected being too great. The experiments were made for the purpose of determining if freedom from stricture had any influence in preventing an ascending infection of the kidney.

"The specimen which I present for your inspection effectually answers this question in the negative. The dog from which this kidney was removed was operated upon November 18, 1899. The left ureter was united to the rectum in the manner described. The peritoneum and loose connective tissue about the ureter were stitched along the line of suture. Nine days after the operation he was found dead. The left kidney was enlarged to double the size of the right. The pelvis of the kidney was dilated and contained pus, the bacteriologic examination of which showed the presence of colon bacilli. The ureter was not dilated, and the opening into the bowel was patent and allowed water injected into the pelvis of the kidney to pass freely into the rectum. The ureterorectal anastomosis was perfect and there was no leakage of urine into the peritoneal cavity. The specimen shows the changes typical of pyelonephritis.

"The infection in this case took place even more quickly than in the experiments where the ureters were buried in the muscles of the bowel and where a certain amount of ureteral stricture existed. So far as this case is concerned, a free flow of urine did not prevent an ascending infection.

"In addition to my experimental work on living animals, I am carefully studying microscopically the course of the ureters, through the dog's bladder wall to see if the direction of the ureters, the muscles with which they are surrounded, or the formation of the ureteral orifice can explain comparative freedom from infection when the ureters are implanted together with the trigonum into the rectum. The results of these studies will be given later when my experimental work is reported in detail.

"We know that Maydl has transplanted the trigonum together with the ureteral orifices into the rectum in a number of cases with success and his patients have lived a number of years and are apparently well. None of these cases have been examined post-morten, and it is not certain that infection of the kidneys has not taken place. The only experimental work upon dogs in which this operation was done that I have been able to find in the literature resulted in the immediate death of the animal, hence an opportunity of studying the condition of the kidneys was not afforded.

"This specimen which I show you now is from a dog where the ureteral orifice and a portion of

the trigonum have been implanted in the rectum on one side and the other ureter cut away from the bladder and anastomosed with the rectum according to the old method I have spoken of. The differences in the two kidneys are apparent to the naked eye. The kidney where the ureteral orifice was implanted is normal in appearance, while the other shows the characteristic changes of pyelonephritis. Bacteriologic examination was negative in the first kidney, and showed large quantities of colon bacilli in the other kidney. The dog lived ten days and died from peritonitis due to a mural abscess.

"The reason for the large primary mortality in animals subjected to Maydl's operation is because of its complexity. I have read a description of the operation a number of times, and I find it far from clear. I have devised an operation for the anastomosis of the trigonum together with its ureteral orifices with the rectum, which is simplicity itself, and any surgeon who can successfully perform an intestinal anastomosis can perform the operation with ease. The majority of the dogs upon which I have operated by this method are living and at some future time will be killed and the condition of their kidneys carefully studied."

Hernias of Cecum and Sigmoid.—The radical cure of hernia consisting of cecum or sigmoid slipped down behind the ordinary hernial sac, has long been tried with but little success. Many surgeons close the wound without attempting reduction or cure. These hernias even when successfully operated on are unusually prone to recur. R. F. Weir (*Med. Record,* Feb. 24, 1900) discusses this subject and suggests an operative procedure giving hope of a permanent cure. As a matter of fact, these hernias are usually of the ascending and descending colon rather than of sigmoid and cecum. These portions of bowel usually uncovered by peritoneum posteriorly, slip down behind the hernial sac and form attachments to the deeper tissues, thus becoming irreducible early in their history. They cannot be positively diagnosticated before operation, but there are a few signs that help. They are most common on the left side in males at or beyond middle life. They usually give a history of early reducibility, but of not being controlled by a truss. Soon they become irreducible, and are then usually scrotal. Because of the frequency of this type, every large irreducible hernia should be approached by the knife with great caution and with full knowledge of the peculiar anatomical relations involved in order to avoid wounding the gut. Often one is at first confused by the presence of enlarged epiploic fringes. Having recognized the postperitoneal gut, what shall be done with it? It is hard or impossible to reduce by mere manipulation. The separation of the gut from its posterior attachments and its return to the abdomen is apt to lead to serious interference with nutrition, and to be followed by gangrene, fecal fistula or perhaps death. To excise the herniated gut and do an anastomosis within the internal ring is too risky. To simply close the wound with the hernia *in situ* is unsatisfactory to both surgeon and patient. Weir suggests the following way out of the difficulty, and has successfully operated on two cases. The posterior wall of the sac, which already is adherent to the front of the herniated gut, is dissected up, beginning at some distance from the gut on all sides. As the gut is reached, it is separated from its posterior connective tissue bed, up to beyond the internal ring. The peritoneal flaps derived from the posterior sac wall are adherent to the gut in front and are turned back and sutured over the posterior raw surfaces. In this manner the gut is completely surrounded by peritoneum and is then easily returned to the abdomen. The remainder of the sac is then dissected up, the edges due to forming the above flaps are sutured together, and then one practically has a sac like the ordinary one and proceeds as in other herniæ with the operation of his choice. Removal of cord and testes helps to obtain a permanent cure. The two cases operated on by this method have thus far passed eight months without sign of recurrence.

Finer Structure of Bacteria.—K. Nakanishi (*Münch. med. Woch.,* Feb. 6, 1900) has obtained some astonishing results with a new staining process which is applied as follows: A saturated solution of methylene blue is dropped on a slide and carefully spread, the excess then wiped away until the glass appears of sky-blue color. The remaining solution is then allowed to dry. The substance to be examined, suspended in some fluid medium in which the stain is freely soluble, has in the meanwhile been placed on a cover-slip, which now is inverted on the slide and at once examined. The results obtained were: (1) Nuclei of polynuclear leucocytes stained only after the cells were dead or had lost their ameboid movements. Large and small mononuclear cells took up the dye poorly. (2) Erythrocytes stained only when abnormal. (3) Malarial parasites showed all details of their internal structure with remarkable clearness, but the chromatin granules in the crescentic bodies were not seen. (4) All bacteria, including even the tubercle and leprosy bacilli, were well colored after life had been destroyed with formaline vapor. When young and grown under favorable circumstances they all appeared as short, mononuclear cells. The protoplasm had more marked affinities for the dye the older the organism, but always appeared homogeneous. The nucleus, which usually was round or oval and small, had a centric position and took on a more purplish color, and would leave the cell in presence of protoplasmic poisons. Great variations were found in the membrane; in some cases it was well developed, in others rudimentary or absent, especially in the young bodies. The mucoid capsule stained well where it was present, not, however, the flagella. Karyokinetic cell-division

could be demonstrated; in some cases the cell did not divide with the nucleus, in others the new organisms remained united by a partition. When the nucleus enlarged and lost its property to stain, it became a spore.

Mulberry as a Diuretic.—The use of the leaves of the mulberry-tree as a diuretic is popular in Siberia. This formula is recommended: Leaves of the mulberry tree, 40 grains to 2 cups of boiling water. Let this steep eight to ten hours in a warm place and take a cupful in the morning and another at night. Continue this for three days. The taste is not disagreeable. The secretion of urine gradually increases: from 54 ounces at the beginning it rises to 62, 72, and finally 88 ounces. The subject of this observation was a man eighty-four years old, who had suffered for ten years with edema of the feet.—(*Bull. gen. de Therapeutique,* Feb. 8, 1900.)

Eulactol.—J. W. Frieser (*Klin. therap. Woch.,* Feb. 11, 1900) insists on the great importance of proper diet in all weakened and convalescent states. The value of concentration is obvious, and this property is best found in the various foods which flood the market. But high nutritive value, easy digestion, agreeable taste, and free solubility are no less important. Eulactol, a preparation made from eggs and milk and containing proteid, fat and carbohydrate, in proper proportions, seems to rank among the best and can be given up to about two ounces daily, in coffee, etc. It is especially indicated in functional or chronic gastric or enteric disease, tuberculosis, scrofula, rachitis, anemia, chlorosis, fevers and senile marasmus.

Observations on Brain Surgery.—After operating on forty-eight brain cases and performing many experiments on animal brains, G. W. Crile publishes (*Med. Record,* Feb. 17, 1900) the following observations. The immediate effect of increased intracranial pressure is not marked until the brain is compressed five to seven per cent. of its volume. Respiration is sooner and more profoundly affected than the blood pressure. Respiration is first slowed, then arrested. The higher the blood pressure, the higher is the intracranial pressure necessary to cause respiratory arrest, and when such arrest has occurred, if the blood pressure be increased respiration may be resumed. Increased intracranial pressure causes slowing of the heart, followed by intermissions and later complete arrest. When pressure persists, the inhibitory mechanism fails, and very rapid heart-action follows. With the brain under pressure, less anesthetic is required to cause surgical anesthesia, and the deeper the anesthesia the earlier and more abruptly respiration fails; both alternating rapid and slow pulse indicate an exhausted cardiac center, a fatal prognosis, and a very strong contraindication to operative procedure. At the same time the vasomotor system is exhausted. During operation an assistant should always be ready to do artificial respiration, and ice and hot water should be at hand for alternate application to chest and abdomen as respiratory stimulants. If respiration ceases and cannot be renewed, the skull should be opened as quickly as possible and the pressure relieved, when normal breathing will almost surely recur. The first effect of blows on the skull, gunshot wounds, rapidly increased intraventricular pressure, etc., is respiratory failure, while the heart continues beating for some minutes. Therefore, artificial respiration is an important first-aid in brain injuries, and since increase of blood pressure favors the return of spontaneous breathing, proper stimulation should be given. There is a well defined area, external to the olfactory tract and in front of the uncinate gyrus, stimulation of which causes arrest of breathing. This area rests directly against the base of the skull and is therefore liable to injury by either direct or indirect violence. In one case, dying of respiratory failure, after a fall, autopsy revealed a marked laceration of just this portion of the brain.

Basophile Granules in Erythrocytes.—While the observation that basophile granules occur in the red blood-cells in many cases of severe anemia is not new, M. Cohn (*Münch. med. Woch.,* Feb. 6, 1900) draws attention to the discordant views as to their significance. To determine whether they result from the degeneration of the nuclei or the cell-protoplasm itself, an artificial anemia was established in several rabbits by drawing off as much as one-third of their blood. The granules were not found at once after venesection, but appeared one or two days later chiefly in polychromatophilic cells, and many of these without granules were also apparent. The late appearance of these changes speak for cell degeneration, rather than breaking down of the nucleus. It is known that large losses of blood are followed after several days by a hydremic condition of the circulating fluid. This is also seen in all forms of anemia except chlorosis, and it is probably that it stands in definite relation with and is the chief causative factor in the cell changes.

Chloroform Narcosis.—A few weeks ago there appeared an article on this topic by Koblanck, in which he describes various symptoms pointing to early asphyxia in narcosis, and in the course of which he cites Czempin as not having properly recognized the significance of these danger signs. Czempin (*Centralbl. f. Gynäkol.,* Feb. 3, 1900) appears and says that Koblanck misquotes him. In his reply, Czempin states that the much advised method of drawing up the epiglottis directly with the finger at the outset of asphyxia, as also recommended by Koblanck, ought not to appear in any text-book on the subject as a means often to be employed. He has himself never practised this method. As a defense of his idea Czempin says that as chloroformed patients breathe exactly as do healthy persons when awake and breathing through their nose, so is it necessary in individuals with obstructed nasal passage

to have a free entrance for air through the mouth. This is attained easily and best by drawing the tongue forward with a silk ligature through the end of the organ. If in deep narcosis, the tongue has fallen back, obstructing the entrance of the larynx, asphyxia results. At this stage it is necessary to free the laryngeal passage. The way to do this is to open the mouth, forcibly if necessary and to draw forward the tongue with the proper forceps. The pushing forward of the jaw will often also accomplish the same thing, indeed, if a tendency exists for the tongue to fall back, it is wise to keep the jaw protruded during the entire anesthesia—otherwise this procedure is not necessary. Another point to which Czempin wishes to call attention is that so often seen in debilitated patients. After a few whiffs of chloroform have been taken they suddenly stop breathing. If shouted at to breathe, they will recommence, but off and on during the giving of the anesthetic they will breathe irregularly or stop at times altogether. Instead of pushing the chloroform, as is so often done at this point, it is wise to desist for a time, for with this poor quality of respiration the heart perceptibly weakens. The author says finally that in old and weak patients he recommends Billroth's formula for the anesthetic: Alcohol 1, ether 2, chloroform 3 parts, to bring down the point of saturation of the drug artificially.

Guaiacum Reaction. — K. Brandenburg (*Münch. med. Woch.*, Feb. 6, 1900) has analyzed pus with the object of determining the nature of the body causing the blue discoloration when in contact with tincture of guaiac. The matter from a cold abscess was treated with chloroform-water. The sediment was filtered off and the remaining turbid fluid treated with acetic acid, the result being a heavy precipitate. It was found that this substance on purifying by repeated solution and precipitation, possessed the reaction to a marked degree. On ultimate analysis the presence of phosphorus and iron could be determined and the body was thus classified among the nucleo-proteids. Animal tissues in general have the property of adding oxygen to easily oxidizable chemicals, but vary considerably in the intensity with which they do this. Nucleo-proteids could also be extracted by simply digesting the various tissues with water; while the resulting compounds actively decomposed hydrogen dioxid they did not give the guaiacum reaction with the sole exception of the preparation obtained from bone-marrow. It thus seems that leucocytes differ chemically from the other cellular elements, but what is more important is the absence of discoloration noted in tissue rich in lymphocytes, *e. g.*, thymus. A positive reaction could also be obtained in many cases with saliva, probably due to the salivary corpuscles, and with purulent sputum and leukemic blood in considerable dilution. It is probable that the nucleo-proteid which has recently been isolated from urine in fevers, jaundice, and other morbid conditions, is not due to leucocytes, but is derived from the fixed tissue-cells since the reaction failed in all cases.

Malaria.—In an exhaustive lecture on this subject before the Italian Association, A. Celli goes deeply into the epidemiology of malaria, discussing the source of infection, the transportation of the germ, the invasion of the disease, the disposition, receptive or otherwise, of the patient, and the prophylaxis to be observed. The address (*Berl. klin. Woch.*, Feb. 5 and 12, 1900) is in substance as follows: (1) Source of infection; man is the medium and the mosquito is the real host of the malarial parasite, for it terminates its asexual life while with man and develops its full sexual existence while in the mosquito. This explains the possibility of the constant development of the plasmodium outside the body of man. The presence of both man and insect is necessary, however, to complete the so-called "infection-cycle;" for the germ, completing one period of its existence in one host, transfers itself to the other in order to develop its further growth, whence it again seeks its original home. No mosquito can infect another; such infection necessarily procedes from man. Therefore malaria is a typical infectious disease. The chief species carrying the germ is the *Anopheles claviger*, which may easily be recognized by the four black spots on its wings! Water and earth can only be considered as secondary or accessory in the infectious process in that they contain the larvæ and eggs of the insects. (2) The transportation of the disease; the name of the disease *mal aria* contains in itself the notion of bad air as the causative factor and it is believed that the disease germs are in the atmosphere in the greatest numbers about dusk and during the night. The germs arise from narrow bordered heaths and become diffused within limited areas. Winds do not scatter them about; but, on the contrary, lessen their number in the atmosphere. Forests serve as centers of origin of the miasma. These facts strengthen the modern theory of the transmission of the disease by the mosquito, inasmuch as this insect lies hidden at daytime, coming out about twilight to pursue its nefarious work; it never flies far from its birthplace and does not fly high in the air; and in a fairly strong breeze does not come out at all. The mosquito furthermore has his domicile in the damp woods and in trees.

The data concerning the epidemics of malaria serve to prove that neither water nor vegetable foods, nor still the inhaled dust, all of which have been given as causes, are to be regarded as causative factors. (3) The invasion of the germ takes place through the skin, it becoming inoculated through the sting of the insect and the sporozoa thus transferred. (4) Not a single epidemic can be fully understood if consideration is not taken of the enormous importance of disposition to, or immunity from, infection. Such disposition or immunity may be divided into organic, local, and social. (*a*) Organic; a chilling of the body dis-

poses to the infection; children especially are prone to catch the disease, the greatest mortality from it being in the ages from five to twenty years. No race is immune. In some malarial localities, however, there are individuals who in spite of all excesses and indiscretions never seem to be attacked; they seem to possess some hereditary immunity. Artificial immunity may be gained by the use of certain drugs, notably quinine and methylene blue. (*b*) Local; there exists no kind of ground which might be designated as unfavorable for the development of the plasmodium. As far as water is concerned, it is necessary in that it supports the life of the larvæ. The great source in this respect is the fresh water ponds, while saline waters—rivers, lakes, bays, etc., opening into the sea, are notably free. (*c*) Social; it need only be tersely stated that social conditions, *i.e.*, food, domicile, clothing, occupation, are great factors in disposing the individual to attack in epidemics or on the other hand in immunizing him from its ravages. (5) Prophylaxis; as is always the case, the diagnosis must first be firmly established by microscopy before a rational prophylaxis can be undertaken. The patients must be isolated, as the disease is certainly an infectious one through the medium of the mosquito. This isolation may take place in any locality where no mosquitoes abound. Disinfection of the blood by means of quinine must be early practised. The only practical method of disinfecting the insects and their larvæ is to destroy both. One of the best preparations to use for this is crude petroleum. It is poured on the marshes and bogs so that the whole sheet of water is covered with a film. Other substances used are the pollen of unopened chrysanthemums and several of the anilin colors. To protect the skin of the body against the insects' attack a soap of turpentine is very efficacious. It is largely used in Italy by officials having to perform night-duty. Sanitary precautions in malarial districts, the regulation of sewerage, the prevention of stagnant water, all serve to keep out the disease. As far as the immunization of an individual visiting an infected district is concerned, all that can be said is to pay close regard to all the points above enumerated and add "*unum facere et alterum non omittere.*"

Carbonic Acid Applications.—The results of the Nauheim treatment on diseases of the heart and circulatory systems have stimulated investigations into methods of obtaining artificial carbonated thermal baths. R. Hatschek describes such a method in the *Wien. klin. Rundschau* (January 28, 1900). He quickly applies a paste of bicarbonate of soda to the body of the patient and follows this with wrapping him in a cloth saturated with weak hydrochloric or acetic acid. By occasionally wetting this cloth with the acidified water, a very lively effervescence is produced and the production of carbonic acid is well developed. It is also worthy of notice that the production of the gas goes on even within the skin, for the paste finds its way through the pores and meeting the acid secretions of the sweat and sebaceous glands is converted into carbonic acid gas. The gas evinces its efficacy directly upon its production by its action on the capillaries and nerve-endings in the skin. Beyond this, its too great activity is somewhat hindered by the cloth wrapped about the patient. The action of the gas is shown by the originally constricted blood vessels and cold, cyanotic extremities returning to their normal state and assuming a ruddy healthy glow. The rubbing and other forms of friction take much longer to accomplish this same result than does the gas when formed in this way. For one application for an adult, about two ounces of sodium bicarbonate were found necessary, producing at the ordinary temperature of the room nearly 16,000 cubic cm. of carbon dioxid. In preparing the paste several teaspoonfuls of warm water should be mixed with it in order not to chill the body before the cloth is applied. The application must be made hurriedly and the parts of the body may remain covered alternately, while the others are being treated with the paste. The acidified solutions are to be markedly thinned and diluted in order that no inflammatory reaction on the part of the skin follows. When properly done, this procedure is at least as good as, and often far better, in its results on the circulation and heart, than the bathing with natural carbonic waters at Nauheim itself.

Treatment of Hysteria.—In the *Indian Medical Record* of Calcutta (January 10, 1900) Surgeon Major R. E. Wrafter of Dehra Dun recommends certain procedures in the treatment of hysteria. The first object is the relief of the patient during the actual paroxysm. If the attack be severe and protracted care is to be taken that the patient does not injure herself. Cold water to the face, fresh air, rubbing the temples with spiritus ætheris comp., are often effectual to stop the paroxysm. It is usually impossible to give medicine by the mouth, as the teeth are either tightly shut or the power of deglutition is lost. Should it be possible, however, it may be advisable to give internally a mixture of spirits chloroformi, spirits ætheris comp., and aqua camphoræ together with tinct. lavendulæ comp. If this cannot be done, an enema of ol. terebinthinæ or tinct. asafœtida may be employed to cut short the attack. In the interval between the attacks, internal medication may be employed to advantage. The indications are to allay the excitability of the nervous system and to improve digestion. In plethoric patients, cathartics, low regimen and regular exercise are useful. In languid patients, tonics are indicated. Myrrh, bromide of potassium and cinchona, a course of mineral waters, daily exercise, tepid bathing, and generous diet will prove very efficacious as adjuncts in the treatment. Aromatic distilled waters are useful as carminatives where flatulency is present. Hysterical patients should never be roughly treated and above all, the physician must always be careful

that no other disease coexist. Some management of the mind looking to its greater stability is also very useful when properly carried out. A woman can often by well-timed firmness on the part of the practitioner, resist the tendency to an attack. In cases of hystero-epilepsy of the ovarian type, the attacks can be arrested at any stage by forcible pressure on one or the other ovary. It is extremely difficult, however, to recognize these cases and to distinguish them from pure epilepsy.

Predetermination of Sex.—This has been a most interesting subject of discussion in the medical journals since the publication of the theories of Dr. Schenck, founded on the belief that the ruling factor was in the kind and amount of food which the mother partook during gestation. A new theory which claims to have been proven in practice is now advanced by Dr. J. G. Davis (*N. Y. Med. Jour.*, Feb. 24, 1900) who reports that she has during the past twenty years been able to predetermine the sex in all cases where an attempt was made, provided her rules were followed. Two failures were easily explainable and aid in proving her theory. The monthly cycle is divided into three parts; one, from three days previous to menstruation until eight days after the cessation of the flow, during which time only girls are produced; second, from the eighth to the tenth day after menstruation, when either boys or girls may be produced; third, from the tenth to the fifteenth day, when only boys may be conceived. During the remaining period she believes a woman to be practically immune to the dangers of conception. In her experiments she has further noticed that when impregnation occurred on the eighth or ninth day, besides the sex being indeterminate, a boy would oftentimes be somewhat effeminate and a girl rather masculine in her characteristics. Thus by the mere practice of self-denial or absolute continence for a certain number of days, the sex of the offspring may be easily predetermined, and happiness brought to many otherwise dissatisfied homes. She founds her theory on the belief that the vibratory law of Nature governs this phenomenon as well as all others, and that the rate of vibration in the female which is higher during ovulation and lower at other times will cause the conception of a girl or boy respectively, according to the vibratory condition in which the mother happens to be at the time of impregnation.

Gastric Ulcer.—Cases of gastric ulcer are, no doubt, frequently diagnosticated as chronic gastritis on account of the similarity of symptoms, but largely due to the lack of a thorough examination of the patient. B. Reed (*Internat. Med. Mag.*, Feb., 1900) points out the important diagnostic features. The three cardinal symptoms are, pain, hemorrhage, and circumscribed tender spots. The pain, as a rule, begins soon after the entrance of food into the stomach and often remains until vomiting occurs, or until the food has been passed on to the intestine. The fact that the pain is absent when the stomach is empty and much less when liquid food only is taken is almost diagnostic. The hemorrhage may be observed by the vomiting of fresh blood, or dark changed blood, or by the passage of tarry stools. Marked circumscribed tenderness in the epigastrium just below the ensiform cartilage and to the left of the median line, and also on the left side of the spine over the origin of one of the last three ribs, is a most constant symptom. Vomiting of food after eating is seen in so many diseases that it is of less diagnostic value. Vomiting usually occurs from one-half to two hours after eating and is followed by cessation of pain. This distinguishes it from carcinoma. An almost constant excess of hydrochloric acid is one of the important corroborative signs of gastric ulcer. The appetite is usually good and may be excessive. Marked anemia is frequently present. The most liable complications are (1) fatal hemorrhage; (2) perforation with localized or general peritonitis, or (3) a subphrenic abscess.

Peripheral Neuritis and Arsenic.—In the *Medical Chronicle* (February, 1900) F. C. Railton has reported four cases of chorea treated by arsenic at the Manchester Clinical Hospital in which serious symptoms of paralysis developed. The ordinary toxic symptoms of stomach trouble, diarrhea, puffiness of the eyes, etc., were noticed in only one of these cases, and the paralysis, which affected the lower extremities principally, came on gradually several days or even weeks after the cessation of treatment and in most cases after the return of the child to its home. All the cases eventually recovered after a very protracted convalescence. On account of the slow elimination of arsenic from the system, he concludes from a wide experience, that an aggregate of 6.3 grains of arsenious acid, even when distributed over a period of three weeks, is sufficient to produce peripheral neuritis in a child.

Parasitic Skin Diseases.—When an antiparasitic drug is applied to the skin in strengths sufficient to be efficacious there is always danger of causing a most annoying dermatitis. G. J. Bucknall (*N. Y. Med. Jour.*, Feb. 24, 1900) points out that in the treatment of parasitic skin lesions, three principles must be observed; first, external irritation, or injurious agents must be avoided; second, substances which cause a roughening of the epidermis should not be used, but a softening agent employed; third, antiparasitic drugs able to destroy the organisms must be thoroughly applied. He believes that these cardinal principles are embodied in a drug—sapodermin—which he has used in a one-per-cent. ointment on many cases of scabies, furunculosis, pediculosis and idiopathic alopecia with most favorable results. This is an albuminate of mercury which has been considered theoretically to be inert, but is found to be highly antiseptic and leaves the skin in a soft, pliable condition.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

PLANT OILS AS FOOD.

THE importance of fat as an ingredient in the human diet needs no restatement. Only too often, however, it is found that individuals who have most need for fats have not the slightest taste for them in the ordinary forms in which they are prepared for consumption, amounting in some instances to positive aversion. But in these cases fats and oils may be taken not only readily, but with positive pleasure. In the warm countries where the disinclination to animal fats is apt to be pronounced, the plant oils, such as olive oil and the various nut oils, are usually favorite articles of diet.

The possibilities latent in vegetable oils as an article of diet are not utilized, especially in this country, to an extent proportionate to their merits. Theoretically we may admit that plant oils are of the greatest nutritive value, but do not realize the practical importance of this fact.

Fat is a substance elaborated by cellular activity in living organisms. Whether the cell that accomplishes the production of the fatty material from indifferent elements, or collects it little by little from the nutritive material supplied to it, be plant or animal, the process and its result are biologically equivalent. The protoplasm of the plant cell is to all intents and purposes exactly the same as that of the animal cell. Analyzed, chemically, after the death of the cell, they are found to be made up of the same substances. It is no wonder, then, that the various products of their activity should resemble each other. Plant oils and animal fats have, it is true, certain characteristic qualities in which they differ from each other. Certain members of the plant series of fat compounds are, however, much more nearly related to certain animal fats than they are to other members of their own series; and, on the other hand, many animal fats resemble others of their own series much less than they do the plant oils. The more fluid fats contain a larger proportion of olein than do the harder fatty substances which are rich in palmitin and stearin. The yellow fats are richer in olein than are the white fats, which owe their color mainly to stearin. Human fat is much richer in olein than most other animal fats and for this reason approaches more nearly many of the vegetable oils.

Clinical experience has shown how beneficial for human consumption are the fish oils, which are also rich in olein. The product is, however, expensive and its preparation for table use requires most careful precautions, as it may have associated with it a number of undesirable substances that make it unpalatable and indigestible, especially for the delicate stomachs of the patients who most need it. The vegetable or plant oils are not open to these objections. Moreover, they can be obtained very cheaply. Modern manufacturing enterprise has made it possible to obtain certain of them in a perfectly neutral state, and much cheaper than even the ordinary animal fats. There seems every reason, then, that their use in the family should be encouraged as much as possible. They represent a most desirable addition to the domestic economy of the modern household, a cheap, clean, eminently nutritious and wholesome fat. This is especially fortunate at this time when fats are not being sufficiently used in the daily dietary.

THE ETIOLOGY OF CANCER.

WE published April 1, 1899, an article by Dr. Roswell Park on the increase of cancer. In this he showed from statistics that malignant disease is every year, throughout the civilized world, claiming more and more victims, and that it has become more of a scourge to humanity than prac-

tically all of the infectious fevers taken together. The increase in the cancer mortality is more than balanced by the decrease in the death-rate from tuberculosis. These concrete statements of Dr. Park very naturally came to the medical world somewhat as a surprise. It had been the custom to think of cancer as an awful, but comparatively rare disease, irretrievably fastened upon mankind, but with no tendencies to vary in its virulence. The discussion that followed Dr. Park's paper, however, has been of great value in establishing more positively his statements. (See p. 324.) There seems to be no possible room for doubt that cancer is very seriously on the increase. If the statistics available on the subject mean anything, this is the undeniable lesson they teach. There are considerations, such as the use of better diagnostic methods and the more careful preparation of mortality reports, which lessen somewhat the force of the deduction from the appalling increase in the death-rate from cancer, but they do not explain it away. On the contrary, they serve to emphasize the fact that the increase of cancer is real, not apparent.

In addition to this increase in the number of cases, there are other striking facts with regard to the affection which have been brought out forcibly during recent years. One of these is that cancer is occurring at an earlier average age than was the case twenty years ago. A number of prominent European clinicians have called attention to this. It is a favorite teaching of Wölfler of Prague, who insists on the greater frequency of cancer, especially of the digestive tract, between the ages of twenty and thirty than was formerly the case. Nothnagel of Vienna is also very strongly of this opinion, and quotes the authority of Billroth, who, shortly before his death, expressed a similar conviction. French surgeons and internal pathologists have also insisted on this same observation.

Another characteristic of cancer that is being widely acknowledged is its tendency to occur by preference in certain localities. It has been pointed out that just as there are "consumption houses" so there are "cancer houses," dwellings in which deaths from this disease occur much more frequently than in neighboring houses. After a death from cancer in a particular house the family in which it has occurred may move out, and one of their successors in the house, in whose family no history of cancer exists, will suffer from the same affliction. When this idea was first advanced with regard to consumption it was scouted as utterly improbable. It is now generally accepted and the acceptance of a like conclusion for cancer houses seems to be one of the coming ideas in medicine. Not only are houses infested with cancer, but special localities somehow seem to favor its development. Certain villages show an undue proportion of cancer patients, and certain streets have become noted for the disproportionate occurrence of cancer along them. There are regions that undoubtedly have the unenviable distinction of being especially liable to the scourge. The work of what may deservedly be called the Buffalo school in the pathology of cancer has served to demonstrate that extreme western New York is one of these distictively unfavored regions.

It is very appropriate, then, that from this part of the country should come some of our most noteworthy advances in the knowledge of malignant disease. The recent report of the New York State Laboratory for the Investigation of Cancer, at Buffalo (see p. 358), shows that with the increased facilities afforded by State aid the good work of advancing our knowledge of cancer is to continue with even greater enthusiasm and the promise of still greater success. The details of the past year's work, as given before the New York Academy of Medicine, shows that the task of investigating the etiology of cancer has, for the first time in this country, been taken up in a thoroughly methodical way. The results so far have been most encouraging. The production by inoculation, with cancerous material from an internal cancer, of a true adenocarcinoma of the mamma in an animal marks an epoch of the American investigation of cancer. The observations and demonstrations of Italian and English experimenters have been successfully repeated at the Buffalo laboratory and everything is in readiness now to advance step by step to ultimate logical conclusions. The blastomycetes theory of the origin of cancer takes on a new lease of life in the light of these successful investigations. The recent observations of Sanfelice have identified the yeast-cells, which in his theory are supposed to be the cause of cancer, with the spherical bodies described by Russell and known as Russell's fuchsin bodies, and probably also with the appearances seen more recently in cancer specimens by Plimmer. This unexpected connection brings out these varied observations with striking force. It serves, too, to show that the investigation of a problem like this from different stand-

points and in different countries may prove of the utmost importance for its ultimate solution. The recent American observations cannot but prove of the greatest service in further elucidating the obscurities that inevitably remain in so involved a question.

The subject is of transcendent importance. The knowledge that cancer is on the increase, that it is occurring in successively younger patients and that it is endemic as well as epidemic, emphasizes the supreme desirability of the most patient investigation of its effective and predisposing causes. There seems every reason to think that American enterprise and inventive ingenuity may prove successful in the solution of a problem that has so far puzzled the medical world.

ECHOES AND NEWS.

NEW YORK.

Yellow Fever at Quarantine.—The steamer "Homer," from Santos, January 31st, via Bahia and St. Lucia, laden with coffee, arrived at quarantine February 24th and reported yellow fever on board, two deaths having occurred on the voyage. One of the victims was a fireman, who died February 5th, and the other a mess-room steward, who died February 9th. Both victims were buried at sea.

Contagious Diseases.—The following cases were reported during the week ending Feb. 24, 1900: Measles, 896 cases and 60 deaths; diphtheria, 285 cases and 50 deaths; laryngeal diphtheria (croup), 17 cases and 14 deaths; scarlet fever, 195 cases and 17 deaths; smallpox, 2 cases; chicken-pox, 24 cases; tuberculosis, 207 cases and 176 deaths; typhoid fever, 25 cases and 10 deaths; cerebrospinal meningitis, 5 deaths. Totals, 1651 cases and 332 deaths.

Doctor and Driver Censured.—The driver of the New York Hospital ambulance which ran over a woman, as narrated in a recent issue, was censured by a coroner's jury on February 19th "for failing to bring his horse to a standstill in time to avoid such accident." And the examining physician at the hospital was censured "for failing to make a thorough examination of deceased before sending her to a ward." The woman sustained a fracture of the skull and other injuries, which resulted fatally.

Obituary.—Dr. James L. Watson died in the Homeopathic Hospital in Brooklyn on February 21st, aged seventy years. He was the last surviving member of the old City Guard of Brooklyn, which was merged into the Twenty-third Regiment. He was graduated from the Pennsylvania Medical College. He served as surgeon in the Civil War and was for some time surgeon-general of the Grand Army of the Republic.—Dr. Joseph M. Creamer died at his home in Brooklyn on February 23rd, in his sixty-fifth year. He was a coroner from 1893 to 1895.

The Congress of Tuberculosis.—The first Congress of Tuberculosis under the auspices of the Medico-Legal Society of this city was opened with a dinner at the Hotel St. Andrew on the evening of February 23rd. The organization of the Congress followed the dinner with Dr. Roberts Bartholow of Philadelphia as Honorary President, Dr. A. N. Bell of Brooklyn as President, and fourteen other physicians as Vice-Presidents. Dr. Charles Denison of Denver is Secretary and Treasurer. Clark Bell, President of the Medico-Legal Society, presided at the dinner.

The Veterinary College.—Recently the American Veterinary College became a department of the New York University and Bellevue Hospital Medical School. A bill has been introduced into the Legislature adopting this department as the State Veterinary College for the Eastern Division of the State. Provision is made for its support by an annual appropriation of $25,000. The State reserves the privilege of sending to the college for instruction, without tuition fee, any designated student who has lived for at least one year east of a line drawn from Port Jervis to Utica, and thence to Ogdensburg, this section of the State being thus designated as the Eastern Division.

Incineration of Garbage.—Dr. Alvah H. Doty has prepared a report in which he favors the passage of the Wagner-Doughty bill for the incineration of the city's garbage. This bill was set before the Senate Cities Committee, at Albany, on February 20th. Dr. Doty states that by the present method of incineration in use in San Francisco, Montreal, Hamburg, Berlin, Bradford, Leeds, Edinburgh and other cities, the garbage, mixed with ashes and other household refuse, can be incinerated for from twelve to sixteen cents a ton. The gases which are formed during the incineration are returned to the fire and destroyed before they can reach the outer air. The small amount of smoke emitted from the chimney is in no way regarded as a nuisance. The process may even be made a revenue-producer. Dr. Doty considers that a number of disposal stations should be situated in different portions of a large city. For this purpose the city should be divided into districts, each having its own disposal works.

Dr. Backus Sustained.—The Board of Managers of Long Island City Hospital have put on record, by a series of resolutions the keen dissatisfaction felt by the Board on account of the failure of Governor Roosevelt to reappoint Dr. Backus as superintendent of the hospital. The Board loyally endorses all of Dr. Backus' official acts, and declares that the method of procedure through which Dr. Backus was retired from the office as manager should be a disappointment and

discouragement to all honorable and manly State officials who give their time and energies in furthering the philanthropic enterprises of the State without reward of any kind whatever, except that which comes through the pleasure of personal identification with good works and the promptings of a right conscience. Against the continuance of such methods the Board respectfully and earnestly protests.

Gov. Roosevelt has relented and appointed Dr. Backus to membership in the Board in place of a member who resigned.

Recovery from Broken Neck.—We recently reported the recovery of a hod-carrier from a broken neck at a hospital in Yonkers. We have now to report the promising convalescence of a gentleman who sustained a fracture of the fifth cervical vertebra in August last while diving off his yacht into shallow water. The X-ray disclosed the fact that the fractured vertebra was pressing heavily against the spinal cord. In September last an incision was made and the laminæ of the fifth and sixth cervical vertebræ were removed. The cord itself was not interfered with, but remained slightly dislocated. At the time of the operation the patient had neither motion nor sensation below the point of injury, indeed, the operation was done without an anesthetic and without any sensation on the part of the patient. There has been slow but gradual improvement in the patient's condition since the operation, and on February 25th he sat upright for the first time in an invalid chair and was able to propel himself about the room. Only certain movements of his fingers and entire mobility of his lower limbs are still uncontrolled by his will. The operation was done by Dr. Abbé at St. Luke's Hospital.

PHILADELPHIA.

Germantown Hospital.—An autograph book sale for the benefit of this hospital has been in progress for several days and a large fund is being raised. A biography of Admiral Dewey, which contained his autograph, was sold for $100, "Richard Carvel" brought $115, and Dr. S. Weir Mitchell's "Hugh Wynne" ran up to $25.

Health Report.—Deaths in the city for the week ending February 24th were 445, a decrease of 58 from the previous week and a decrease of 194 as compared with the corresponding week of last year. Contagious diseases: Diphtheria, 86 cases, 19 deaths; scarlet fever, 56 cases, no deaths; typhoid fever, 110 cases, 15 deaths. Typhoid fever is steadily increasing.
